Repaglinide has a bioavailability of 56% and is rapidly absorbed and excreted.[199] Its maximal serum concentration (C_{max}) occurs at ~1 hour, and its half-life is 1 hour. Repaglinide is highly (>98%) protein bound (volume of distribution, 31 L). It is completely metabolized (via cytochrome P-450 [CYP] 3A4 and 2C8) by the liver to inactive products, with 90% excreted in the feces and 8% excreted in urine. Nateglinide has a bioavailability of 73%.[198,199] It is rapidly absorbed, with a C_{max} occurring within 1 hour of dosing and a half-life of 1.5 hours. Nateglinide is metabolized (CYP2C9, 70%; CYP3A4, 30%) to

less potent compounds, which are 75% excreted in the urine and 10% in the feces. Sixteen percent is excreted unchanged in the urine. It is highly (98%) protein bound, primarily to albumin, and, to a lesser extent, to α_1-acid glycoprotein.

ADVERSE EFFECTS

Mild hypoglycemia may occur, particularly if patients delay or forget to eat after the dose. A weight gain of 1.98 to 6.61 pounds (0.9–3 kg) compared with baseline has been observed.[200] Rare side effects include elevated hepatic enzymes and hypersensitivity reactions. There has been at least one case report of repaglinide-induced hepatic toxicity.[198]

CONTRAINDICATIONS AND PRECAUTIONS

Because a functioning pancreas is required, these agents should not be used in people with type 1 diabetes. They should be used with caution in patients with liver dysfunction. They are contraindicated for use in patients with DKA. Repaglinide clearance is reduced in patients with severe renal insufficiency, but may still be used safely at a reduced dose.[199] The clearance of nateglinide is not affected in patients with moderate-to-severe renal insufficiency.[201]

DRUG INTERACTIONS

Clinically relevant drug interactions include those that occur when these drugs are taken in combination with other glucose-lowering agents or drugs known to induce or inhibit their metabolism.[198] Therefore, BG levels should be closely monitored when either drug is taken in combination with other agents known to lower BG or affect their metabolism. Repaglinide is metabolized by CYP2C8 and 3A4.[199] Studies have shown that repaglinide has no pharmacokinetic effects on digoxin or warfarin. Gemfibrozil should be avoided in combination with repaglinide owing to the risk of hypoglycemia. The combination of gemfibrozil and itraconazole synergistically inhibits repaglinide metabolism and should be avoided. Concomitant use of clopidogrel may result in increased serum concentrations of

repaglinide; therefore, dose reduction of repaglinide may be required. Cyclosporine inhibits the metabolism of repaglinide, causing increased serum concentrations of repaglinide; therefore, a dose reduction may be required. Nateglinide is metabolized largely by CYP2C9 (70%) and to a lesser extent by 3A4 (30%).[201] When evaluated in clinical studies, there were no clinically relevant interactions with nateglinide and glyburide, metformin, digoxin, diclofenac, or warfarin. Concomitant use of oral systemic azole antifungals should be used cautiously because of the potential for increased hypoglycemic effects. Fibric acid derivatives including fenofibrate, clofibrate, and gemfibrozil may increase the effects of nateglinide. Concomitant use of either repaglinide or nateglinide with rifampin may lower their efficacy.[202]

EFFICACY

The efficacy of repaglinide is comparable to that of metformin and the sulfonylureas.[198] When used as monotherapy, the mean decrease in FPG, postprandial glucose, and the A_{1c} values were 61 mg/dL, 104 mg/dL, and 1.7%, respectively, compared with placebo (−31.0 mg/dL, −47.6 mg/dL, and −0.6% compared with baseline).[199] Nateglinide as monotherapy results in a mean decrease in FPG and A_{1c} of 13.6 mg/dL and 0.7%, respectively, compared with placebo (−4.5 mg/dL and −0.5% compared with baseline).[198,199] In comparison with metformin monotherapy, both drugs produce a similar or slightly smaller reduction in A_{1c}.

DOSAGE AND CLINICAL USE

Repaglinide and nateglinide are approved to treat people with type 2 diabetes as monotherapy or in combination with metformin or a TZD.[198,199] Because they have the same mechanism of action as do the sulfonylureas, combining these agents does not produce any additional benefit. The agents are usually added to therapy for patients with postprandial hyperglycemia, particularly nateglinide. When repaglinide is used as the initial treatment in patients who are naive to oral antidiabetic therapy or in patients with A_{1c} values <8%,

the recommended starting dose is 0.5 mg 15 to 30 minutes before eating up to four times a day. When used in patients who have failed sulfonylureas or in those with A_{1c} values >8%, the initial dose is 1 to 2 mg with each meal up to four times a day. Doses can be titrated weekly at a rate of 1 mg/meal to a maximum of 4 mg/dose or 16 mg/day. Repaglinide should be initiated at a 0.5-mg dose in patients with severe renal dysfunction and should be titrated cautiously in patients with liver dysfunction. The recommended starting dose of nateglinide is 120 mg tid 0 to 30 minutes before meals. For patients close to their A_{1c} goal, a dose of 60 mg tid may be used. Doses should be omitted if a meal is skipped and added if an extra meal is ingested (repaglinide only). There are no dosage adjustments required for nateglinide in patients with renal or hepatic insufficiency.[73,203] Owing to the frequent dosing, risk of hypoglycemia, and weight gain, these medications are not routinely recommended by the ADA or AACE guidelines as first-line management.

Sulfonylureas

Until metformin and other antidiabetic agents became available in the United States, sulfonylureas were the first-line pharmacologic treatment for people with type 2 diabetes who had failed diet and exercise therapy. Six sulfonylureas are available in the United States. The three first-generation sulfonylureas (chlorpropamide, tolazamide, and tolbutamide) are considered equally effective despite differences in their pharmacokinetic properties and adverse effect profiles (see the following discussion and Tables 53-25 and 53-26); however, owing to the increased risk of hypoglycemia, these agents have fallen out of favor and are not discussed in detail.

Glipizide and glyburide, two second-generation sulfonylureas, were first introduced into the United States in May 1984. Glimepiride was approved for use in 1995. Despite being more potent than the first-generation sulfonylureas, these second-generation sulfonylureas are clinically equivalent to the first-generation sulfonylureas, however, they have a decreased risk of adverse

effects. Their duration of activity allows for once- or twice-daily dosing.

MECHANISM OF ACTION

Sulfonylureas stimulate the release of insulin from pancreatic β cells and enhance β-cell sensitivity to glucose. A specific sulfonylurea receptor closely linked to the ATP-sensitive potassium ion channel exists on the β cell. Sulfonylureas inhibit this potassium ion channel, thus blocking the efflux of potassium and lowering the membrane potential to cause depolarization. The voltage-dependent calcium channels then open, increasing intracellular calcium concentration. The increased intracellular concentration of calcium ultimately stimulates preformed insulin secretion. In addition, sulfonylureas can normalize hepatic glucose production and enhance peripheral glucose disposal.[204]

PHARMACOKINETICS

The duration of hypoglycemic activity is related to the half-life of these compounds only in very general terms and may correlate poorly in some cases.[205–207] All sulfonylureas are highly protein bound (90%–100%), mainly to albumin. Binding characteristics, however, vary among individual sulfonylureas. Food does not impair the extent of drug absorption but may delay the time to peak levels of some agents. The relationship between sulfonylurea doses and their BG-lowering effect remains unclear. Studies of glyburide and glipizide suggest that these agents may operate within a narrow range of plasma concentrations that may be achieved with low (10 mg/day) doses.[207] The maximal recommended daily doses of 40 mg for glipizide and 20 mg for glyburide may therefore not be more effective and may decrease β-cell function.[204]

Glipizide is an intermediate-acting second-generation agent with a half-life of 2 to 4 hours, but with a duration of action of 12 to 24 hours. Patients receiving <20 mg/day may require only once-daily dosing. Food delays its rate of absorption, but not its bioavailability. Glipizide should be taken 30 minutes before meals. The onset of

action occurs in 90 minutes, and the maximum decrease in serum glucose occurs within 2 to 3 hours. Glipizide is extensively metabolized by the liver to inactive products that are eliminated primarily by the kidney.[208] An ER formulation of glipizide also is available.

Glyburide is a longer-acting second-generation agent similar to glipizide. The half-life is ~1.5 to 4 hours after single-dose studies and up to 13.7 hours when chronically administered.[209] Nevertheless, as with glipizide, the duration of action can last for up to 24 hours in many patients, allowing for once-daily dosing with small-to-intermediate doses (<15 mg). Food does not delay the rate or extent of absorption. The onset of action is 2 hours, and the maximum decrease in serum glucose occurs within 3 to 4 hours. Glyburide is metabolized completely by the liver to two weakly active metabolites, half of which are excreted in the urine and feces. A micronized formulation is available (eg, Glynase® PresTab®), but it is not bioequivalent to the conventionally formulated tablets. Thus, patients switched between the conventional form and the micronized product must be carefully monitored and the dose titrated again.

Glimepiride is a long-acting second-generation sulfonylurea. Its half-life is 9 hours and its duration of action is 24 hours, allowing for once-daily dosing.[210] The administration of glimepiride with food slightly decreases the area under the plasma concentration–time curve (AUC) and slightly increases the time to peak concentration. Its peak effect on plasma glucose concentrations is observed 2 to 3 hours after each dose. Glimepiride is completely metabolized by the liver, and its principal metabolite has 30% of the activity of the parent drug. Metabolites are excreted in feces and urine. Interestingly, research suggests that the sulfonylureas may close ATP-sensitive potassium channels in cardiac tissue, similar to their action at the β cell. In the heart, this effect could prevent vasodilation during an ischemic episode (ie, ischemic preconditioning).[89]

ADVERSE EFFECTS

The primary side effects of the sulfonylureas are hypoglycemia (particularly for those that are long acting, see Case 53-16, Question 2, and Case 53-18, Question 6) and weight gain (~4.41 pounds [2 kg]).[211] Other adverse effects attributed to the sulfonylureas generally are so infrequent and mild that <2% of patients discontinue these agents because of them. In general, the type, incidence, and severity of reported side effects are similar for all the sulfonylureas. An important exception is chlorpropamide, which has several unique adverse effects (see following discussion). Adverse reactions to the sulfonylureas include GI symptoms (nausea, fullness, and bloating that can be relieved if taken with meals), rare blood dyscrasias, allergic dermatologic reactions and photosensitivity, hepatotoxicity, and hyponatremia (also see Case 53-16).[204]

CONTRAINDICATIONS AND PRECAUTIONS

Contraindications and precautions to the use of sulfonylureas include the following:

1. Type 1 diabetes
2. Pregnancy or breast-feeding, because these agents (except glyburide) can cross the placental barrier and can be excreted into breast milk
3. Documented hypersensitivity to sulfonylureas
4. Severe hepatic or renal dysfunction
5. Severe, acute intercurrent illness (eg, infection, MI), surgery, or other stress that can unduly affect BG control, in which case insulin therapy should be used
6. Glucose-6-phosphate-dehydrogenase (G6PD) deficiency: Patients with this deficiency may be at risk for hemolytic anemia if they take chlorpropamide; consider using a nonsulfonylurea medication as an alternative.

DRUG INTERACTIONS

Drug interactions with sulfonylureas have a pharmacodynamic or pharmacokinetic basis. Pharmacodynamic interactions are

discussed later in this chapter in sections addressing Drug-Induced Hypoglycemia and Drug-Induced Hyperglycemia. Most of the reported pharmacokinetic drug interactions with the sulfonylureas involve chlorpropamide and tolbutamide. Because most of the clinically significant interactions occur with drugs that alter liver metabolism or urinary excretion, possible interactions with all of the sulfonylureas must be anticipated, even though the outcomes may be quite different. Glipizide and glyburide also differ from the first-generation agents in that they are highly bound to albumin at nonionic rather than at ionic sites.[201] On this basis, these agents are unlikely to interact with other highly protein-bound drugs, such as phenylbutazone, salicylates, or certain sulfonamide antibiotics that have been reported to enhance the effects of the first-generation sulfonylureas. These highly protein-bound drugs, however, seem to interact with the sulfonylureas by altering their hepatic metabolism as well. Therefore, glipizide and glyburide should be used cautiously with drugs reported to interact with first-generation sulfonylureas. Sulfonylureas are CYP2C9 substrates; therefore, coadministration with a medication that is an inhibitor or inducer of CYP2C9 will increase or decrease levels of sulfonylurea medications, respectively.[212]

EFFICACY

As with metformin, the sulfonylureas decrease the A_{1c} by 1.5% to 1.7% and the FPG by 50% to 70%. With time and increased duration of type 2 diabetes, the pancreas may respond less to a sulfonylurea. Whether sulfonylureas actually contribute to β-cell dysfunction and decline remains to be clearly determined.[62]

DOSAGE AND CLINICAL USE

The sulfonylureas are effective, inexpensive, and easy to titrate. Sulfonylureas may be used as add-on therapy to patients unable to achieve BG goals on metformin monotherapy, especially when cost may be a burden to the patient.[90] In the United States, second-generation sulfonylureas are preferred owing to their more tolerable

adverse event profile. Similar to the other antidiabetic agents discussed, sulfonylureas may also be considered as monotherapy in patients with contraindications to metformin. The doses of the sulfonylureas are displayed in **Table 53-26**. As a general rule, patients should be started with low doses and titrated upward every 1 to 2 weeks until the desired goal is achieved. Exceeding maximal doses will most likely potentiate increased adverse drug reaction (ADR) without an increase in efficacy (see Case 53-18, Questions 5 and 6).

Thiazolidinediones

MECHANISM OF ACTION

The two available TZDs in the United States, rosiglitazone and pioglitazone, are often referred to as *insulin sensitizers*. The proposed mechanism of action for TZDs involves the medication binding to and activating a nuclear receptor (peroxisome proliferator-activated receptor-γ [PPAR-γ]), which is expressed in many insulin-sensitive tissues, including adipose, skeletal muscle, and liver tissue.[213] PPAR-γ regulates transcription of the genes that influence glucose and lipid metabolism. PPAR-γ stimulation increases the transcription of GLUT-4, a glucose transporter that stimulates glucose uptake[213] and insulin sensitivity.

Pioglitazone also activates PPAR-α, which inhibits the transcription of tumor necrosis factor-α-induced vascular cell adhesion molecule (VCAM-1).[214] This dual effect results in increased HDL and lowered triglycerides. PPAR-α stimulation may also have anti-inflammatory effects.[90,203]

TZDs either directly or indirectly sensitize adipose tissue to insulin action.[90,203] The effects may include stimulating apoptosis of large adipocytes, increasing the number of small adipose cells, and promoting fatty acid uptake and storage in adipose tissue. The subsequent reduction in free circulating fatty acids may spare other insulin-sensitive tissues (eg, liver, skeletal muscle, and β cells) from the effects of lipotoxicity. TZDs also lower expression of tumor

necrosis factor-α, a cytokine produced by adipose tissue that may contribute to insulin resistance and fatty acid release.[203] Other adipokines are likely involved, including adiponectin, resistin, and leptin.[90,190] TZD interaction with adipocytes may be their primary mechanism of action in sensitizing other tissues to insulin action. As with metformin, TZDs have been shown to directly stimulate the 5' adenosine monophosphate-activated protein kinase (AMPK) pathway in liver and adipose tissue, resulting in a lowering of glucose and free fatty acids.[90,203]

Other favorable effects of TZDs that may be beneficial in patients with type 2 diabetes and metabolic syndrome include inhibition of vascular smooth muscle cell proliferation, improved endothelial function, decreased microalbumin excretion, and enhanced fibrinolysis.[215] Despite these improved surrogate markers, the data regarding TZDs and vascular risk are mixed and controversial. In 2009, the FDA added language to the label for rosiglitazone indicating an increased risk of angina and MI. The FDA and GlaxoSmithKline instituted a risk evaluation and management strategy (REMS) to restrict the distribution and prescribing of rosiglitazone. The REMS status was however changed in 2014 to allow for the prescribing and filling of prescriptions of rosiglitazone.

PHARMACOKINETICS

Rosiglitazone is completely absorbed, with peak plasma concentrations reached in ~1 hour.[213] Pioglitazone has a bioavailability of 83%, with peak plasma concentrations reached within 2 hours.[215] Food delays the time to peak concentration, but does not alter the extent of absorption of either drug. Both TZDs are extensively (>99%) protein bound, primarily to albumin. The plasma elimination half-life of rosiglitazone is 3 to 4 hours.[213] Pioglitazone has a serum half-life of 3 to 7 hours, and its metabolites have a serum half-life of 16 to 24 hours.[215] Rosiglitazone is extensively metabolized in the liver by CYP2C8 and to a much lesser extent by 2C9. Its conjugated metabolites are considerably less potent than is the parent drug, and are excreted two-thirds in urine and one-third in

feces.[90,213] Pioglitazone is hepatically metabolized, mainly by CYP2C8 and 3A4, and to a lesser degree by CYP1A1, to three active metabolites; however, the main metabolites found in serum are M-III and M-IV. Approximately 15% to 30% of the dose is recovered in the urine as metabolites, with the remainder excreted either into the bile as unchanged drug or into the feces as metabolites.[213,215]

Because the action of the TZDs relies on gene transcription and protein production, the onset and duration of action are unrelated to the plasma half-life. The onset of their effect occurs in 1 to 2 weeks, although maximal effects are not usually seen before 8 to 12 weeks. No dose adjustment is necessary in patients with renal impairment. There is no dose adjustment needed for hepatic impairment with pioglitazone; however, rosiglitazone should be avoided in patients with moderate-to-severe hepatic impairment.[216–218]

ADVERSE EFFECTS

Hepatotoxicity

Liver failure has been very rarely reported with either rosiglitazone or pioglitazone, although causality in most cases remains uncertain.[219] For both drugs, monitoring of liver function tests (LFTs) is recommended at baseline, and then periodically thereafter (see section on Contraindications and Precautions). One study suggests that LFTs should be ordered before therapy, every 1 month for the first year, and periodically thereafter for both pioglitazone and rosiglitazone.[90,203]

Hematologic effects

TZD therapy may result in small decreases in hemoglobin and hematocrit and, infrequently, anemia.[90] These effects may be attributable to dilutional effects (see subsequent text).

Weight gain

Dose-related weight gain (4.41–6.61 pounds [2–3 kg] for every 1% decrease in A_{1c}) has been seen with rosiglitazone and pioglitazone.[90,203] Weight gain is likely caused by fluid retention or fat accumulation. The weight gain seems to be associated with an increase in peripheral adipose tissue along with a reduction in visceral adiposity.[90]

Vascular and cardiovascular effects

Increases in plasma volume and peripheral edema (4%–6%), possibly caused by increased endothelial cell permeability, occur with the TZDs.[213,215] The incidence of peripheral edema is greatly increased when TZDs are used in combination with insulin.

The FDA added black box warnings to rosiglitazone and pioglitazone based on the association of their use with an increased risk of developing or exacerbating HF in patients with type 2 diabetes.[220] TZDs are contraindicated for use in patients with New York Heart Association (NYHA) class III or IV HF and are not recommended in patients with acute or systemic HF. TZDs should be used with caution in patients with preexisting edema, which may increase the risk of developing new-onset HF or exacerbating preexisting HF (see Case 53-15).

CV outcomes evaluating the risk of MI and stroke have been studied with TZDs. Pioglitazone for 3 years with type 2 DM and a history of MI, stroke, or percutaneous coronary intervention (PCI) may reduce the risk of all-cause mortality, nonfatal MI, and stroke.[220-223] Pioglitazone does not appear to increase the risk of MI or mortality.[224] In the RECORD trial, rosiglitazone did not have an overall impact on CV morbidity or mortality.[225–227] Meta-analysis and retrospective observational studies have, however, suggested that rosiglitazone is associated with risk of MI,[227] but not for overall CV or all-cause mortality.[62] Rosiglitazone has also been shown to increase LDL levels.[213,215]

Other effects

Hypersensitivity reactions including rash, pruritus, urticaria, angioedema, anaphylactic reaction, and Stevens–Johnson syndrome have been rarely reported with rosiglitazone.[213,215,228] Macular edema has been rarely reported with TZDs.[229] Patients experiencing changes or worsening in vision should be referred to an ophthalmologist for follow-up. In some cases, macular edema improved or resolved after discontinuation of TZD therapy.[230]

Pioglitazone has been associated with an increased risk of bladder cancer compared to the general population, and is contraindicated in patients with bladder cancer.[230] In patients with previous history of bladder cancer, the need for use of pioglitazone for glycemic control must outweigh the potential recurrence of bladder cancer.[230] The FDA has released a safety communication warning that the use of pioglitazone for >1 year may increase the risk of bladder cancer.[230] Recently analyzed 10-year findings show no statistically significant increase in bladder cancer, but a risk as previously identified cannot be ruled out. This meta-analysis identified a possible increased risk of pancreatic and prostate cancer. Monitoring for causal effect of cancers should be continued.[231–234]

An increased risk of distal limb bone fractures (eg, forearm, hand, wrist, foot, and ankle) and bone loss have been observed in females receiving TZDs.[233,234] Males may also be at increased fracture risk, but the evidence is not as strong.[235] The mechanism is thought to be reduced osteoblast differentiation as a result of increased adipogenesis in the bone marrow.[213] The potential for fractures in older female patients and patients on chronic steroids should be carefully considered before using a TZD.

CONTRAINDICATIONS AND PRECAUTIONS

- *Type 1 diabetes:* Because insulin is required for their action, TZDs should not be used in people with type 1 diabetes.
- *Patients with type 2 diabetes using insulin:* TZDs should be used with caution because of the increased risk of developing edema.
- *Preexisting hepatic disease:* Pioglitazone and rosiglitazone should not be used in patients whose alanine aminotransferase (ALT) is

>2.5 times normal. TZDs should be discontinued if the ALT is more than three times normal, if serum bilirubin levels begin to rise, or if the patient reports of any symptoms that could be attributed to hepatitis (eg, fatigue, nausea, vomiting, abdominal pain, and dark urine).

- *Symptomatic or severe (NYHA classes III and IV) HF*: See previous discussion.
- *Myocardial ischemia* (rosiglitazone only): See previous discussion.
- *Premenopausal anovulatory females:* TZDs may cause resumption of ovulation and menstruation in females with polycystic ovarian syndrome, placing these patients at risk for an unwanted pregnancy.
- *History of hypersensitivity to TZDs*
- *Patients with osteoporosis or at risk for bone fractures* (eg, chronic steroid use)
- *Drugs metabolized by CYP3A4:* See the section on Drug Interactions for further details.
- *Patients with a current or previous history of bladder cancer: Such patients should not use TZDs.*
- *Macular edema:* Patients should receive regular eye examinations to evaluate acute visual changes.

DRUG INTERACTIONS

Coadministration of a TZD with other antidiabetic medications or insulin does not alter the pharmacokinetics of either drug, but may increase the patient's risk for hypoglycemia. Pioglitazone induces CYP3A4 and may, therefore, decrease the effectiveness of other drugs metabolized by this enzyme, such as estrogens, cyclosporine, tacrolimus, and β-hydroxy-β-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors. Ketoconazole may significantly inhibit the metabolism of pioglitazone.[215] Patients taking oral contraceptives or estrogen-replacement therapy should be informed of the possible risk of decreased effectiveness of estrogen therapy. Rosiglitazone does not seem to inhibit any of the major CYP enzymes.[236] Rifampin

decreases the AUC for both rosiglitazone and pioglitazone, although the clinical significance of this interaction is unknown. Pioglitazone is a substrate of CYP2C8; therefore, interactions may occur when administered with drugs that inhibit or induce CYP2C8.[213] The maximum dose of pioglitazone is 15 mg once a day if given with a strong CYP2C8 inhibitor.[236] Gemfibrozil significantly increases the AUC of both drugs. For patients receiving both a TZD and a gemfibrozil, a dose reduction of the TZD may be warranted.[90,203]

EFFICACY

The effects of TZDs on A_{1c} and FPG are intermediate between those of acarbose and the sulfonylureas or metformin.[213,215] When combined with other antidiabetic agents in a patient with poorly controlled type 2 diabetes, one can expect to see an augmented effect on the A_{1c} (0.9%–1.3% decrease with a sulfonylurea, 0.8%–1.0% decrease with metformin, and 0.7%–1.0% decrease with insulin).[237] When added to the therapy for a patient with type 2 diabetes taking insulin, rosiglitazone and pioglitazone can enhance glycemic control (~0.6% lower with pioglitazone) while decreasing insulin requirements; however, weight gain (>6.61 pounds [3 kg]) and increased edema will likely occur.[90,213,215] Individuals who are minimally responsive or unresponsive to TZD therapy may include those who are not obese and have lower levels of endogenous insulin.

Other potential benefits of the TZDs are their favorable, but variable, effects on lipids.[213] Pioglitazone and, to a lesser extent, rosiglitazone may decrease triglycerides. Both drugs may increase HDL-C levels by 10%. Rosiglitazone has been observed to increase LDL-C by 8% to 16%, whereas pioglitazone may not affect LDL-C. As noted, TZD therapy has been associated with weight gain, and this may be substantial when used in combination with sulfonylureas or insulin.

DOSAGE AND CLINICAL USE

Patients who are unable to take or have failed metformin or sulfonylurea monotherapy or who have not responded to dipeptidyl peptidase-4 (DPP-IV) inhibitor or sodium–glucose transporter 2 (SGLT-2) inhibitor therapy may be candidates for TZDs. TZDs are also a cost-effective therapy for patients with financial insecurity and can be used in patients unwilling to inject. For monotherapy or combination therapy with a sulfonylurea, metformin, or insulin, the starting dose for pioglitazone is 15 or 30 mg once daily with or without food. The dose can be titrated up to a maximum of 45 mg/day.[215] The starting dose for rosiglitazone is 4 mg given once daily or in divided doses. The dose may be increased after 8 to 12 weeks if adequate response is not seen. The maximum daily dose is 8 mg.[238]

α-Glucosidase Inhibitors

MECHANISM OF ACTION

The α-glucosidase inhibitors, acarbose[239] and miglitol,[238] reversibly inhibit glucosidases present in the brush border of the mucosa of the small intestine. These enzymes break down complex polysaccharides and disaccharides into glucose and other absorbable monosaccharides. Enzyme inhibition delays carbohydrate digestion and subsequent glucose absorption. Postprandial BG concentrations are therefore lowered when these agents are taken with a meal containing complex carbohydrates.

PHARMACOKINETICS

Acarbose is minimally absorbed from the GI tract, with an oral bioavailability of the parent drug of <2.0%.[239] It is extensively metabolized by GI amylases to inactive metabolites. The peak plasma concentration occurs in ~1 hour, and the elimination half-life for acarbose is 2 hours, although there may be a longer terminal half-life. Unlike acarbose, miglitol is absorbed. Absorption of miglitol is saturable at higher doses (>25 mg), and peak concentration occurs in 2 to 3 hours.[238,239] The drug is primarily distributed in

extracellular fluids and is not metabolized. After a 25-mg dose, 95% of the drug is excreted unchanged by the kidneys within 24 hours.

ADVERSE EFFECTS

Flatulence, diarrhea, and abdominal pain are the most frequently reported adverse effects of α-glucosidase inhibitors.[240] In placebo-controlled trials of acarbose, these ADRs were experienced by 74%, 31%, and 19% of subjects, respectively. GI side effects are attributable to fermentation of unabsorbed carbohydrate in the small intestine, and can be minimized by slowly titrating the dose of either agent. GI discomfort usually improves with continued therapy because induction of the α-glucosidase enzymes occurs in the distal jejunum and terminal ileum.

In studies using doses of acarbose 300 mg/day or more, a transient increase in serum hepatic transaminases was reported.[238,239] The manufacturer recommends monitoring hepatic transaminases every 3 months for the first year of therapy and periodically thereafter. If an elevation of serum transaminases occurs, the dose should be decreased or discontinued if elevations persist. Because miglitol is not metabolized, it does not seem to affect hepatic function.

CONTRAINDICATIONS AND PRECAUTIONS

Acarbose and miglitol are contraindicated with known hypersensitivity to the medications.[238,239] Both medications are contraindicated in patients with DKA, and acarbose is contraindicated in patients with cirrhosis.

Gastrointestinal conditions

Because of their profound GI effects (flatulence and diarrhea), acarbose and miglitol are contraindicated in patients with malabsorption, inflammatory bowel disease, colonic ulceration or other marked disorders of digestion or absorption, or with intestinal obstruction.[238,239]

Renal impairment

Acarbose has not been studied in patients with severe renal impairment (SCr >2.0 mg/dL) and should not be used in these patients.[209] There is little information with regard to safety of the use of miglitol in patients with a CrCl <25 mL/minute; therefore, its use is contraindicated in these patients.[238–240]

DRUG INTERACTIONS

Patients who use acarbose or miglitol in combination with other antidiabetic agents may experience hypoglycemia. These reactions should be treated with dextrose because acarbose may limit the availability of the disaccharide sucrose (table sugar). Because acarbose and miglitol delay carbohydrate passage through the bowel, they could influence the absorption kinetics of concomitantly administered drugs. Conversely, because their own absorption may be diminished by digestive enzyme preparations and charcoal, they should not be taken concomitantly with these agents.[239] The bioavailability of digoxin can be reduced, and may require dose adjustment. Miglitol decreases the bioavailability of ranitidine and propranolol by 60% and 40%, respectively.[238,239]

EFFICACY

By delaying the absorption of glucose after ingestion of complex carbohydrates and disaccharides, the α-glucosidase inhibitors can lower postprandial plasma glucose concentrations in patients with type 2 diabetes by 25 to 50 mg/dL.[238,239] FPG concentrations remain unchanged or are slightly lowered (20–30 mg/dL), but this effect may be related to decreased glucose toxicity, which improves insulin secretion and action. Mean A_{1c} values decline by 0.3% to 0.7%. Acarbose and miglitol have no effect on weight or lipid profiles.[238,239]

DOSAGE AND CLINICAL USE

Because of limited effects on A_{1c} and their side effect profile, α-glucosidase inhibitors are used infrequently and, when used, are usually given as add-on therapy in patients who have failed

monotherapy or combination therapy with other oral antidiabetic agents. The recommended initial dose of either drug is up to 25 mg tid, taken at the start of each meal.[15] The dosage of acarbose can be gradually increased (eg, 25 mg/meal) every 4 to 8 weeks to a maximum of 50 mg tid for individuals weighing ≤132.28 pounds (60 kg), or 100 mg tid for individuals weighing >132.28 pounds (60 kg). The dose for miglitol is titrated up after 4 to 8 weeks to a dose of 50 to 100 mg tid if needed, regardless of a patient's weight. A maximal response is observed at 6 months.

Incretin-Based Therapies

Incretins are insulinotropic hormones secreted from specialized neuroendocrine cells in the small intestinal mucosa in response to carbohydrate ingestion and absorption.[241] The two hormones accounting for most incretin effects are glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide-1 (GLP-1). GIP and GLP-1 stimulate pancreatic β cells in a glucose-dependent manner, contributing to the early-phase insulin response. GLP-1 also inhibits pancreatic α-cells, thus reducing glucagon secretion and hepatic glucose production. Incretin action is efficient, but short lived. As they enter the blood vessels, incretins undergo rapid metabolism via proteolytic cleavage by DPP-4 to inactive metabolites. Thus, only small amounts are needed to exert their effects on glucose metabolism.

Glucagon-Like Peptide-1 Agonists (Mimetics/Analogs)

The available glucagon-like peptide-1 receptor agonists (GLP-1RAs) in the United States include exenatide, ER exenatide, liraglutide, lixisenatide, dulaglutide, semaglutide (both oral and injectable). The formulations available are a once-daily injection (liraglutide), twice-daily injection (exenatide), once-weekly injections (ER exenatide, dulaglutide, and semaglutide) and once-daily oral tablet

(semaglutide). Albiglutide was previously available; however, it was removed from the market because of limited prescribing and poor market share as of August 2017. The ADA recommends GLP-1 agonists as first-line injectable therapy in patients with type 2 diabetes, especially in scenarios where hypoglycemia, ASCVD, or weight loss is seen. AACE recommends that GLP-1 agonists be used after patients on metformin therapy do not receive glycemic goals or if they cannot tolerate metformin. Liraglutide has been studied as an adjunct to insulin therapy in patients with type 1 diabetes to minimize weight gain, but is not currently recommended for routine use in this patient population.[242]

MECHANISM OF ACTION

GLP-1 mimetics and analogs have stability in the presence of DPP-4, resulting in a longer duration of action than does endogenous GLP-1. These agents augment early- or first-phase insulin response in response to elevated glucose concentrations (ie, glucose dependent), moderate glucagon secretion, and decrease hepatic glucose production without impairing the normal glucagon response to hypoglycemia. They slow gastric emptying, thereby reducing the rate at which glucose is absorbed. In addition, they suppress appetite, which may contribute to the prevention of weight gain and the weight loss (3.31–11.02 pounds [1.5–5 kg]) observed in patients. A promising action of these agents is their potential to increase β-cell mass and preservation, which has been shown in animal models.

PHARMACOKINETICS

After SC injection, exenatide reaches peak plasma concentrations in 2.1 hours.[243] The median peak plasma level for lixisenatide is achieved between 1 and 3.5 hours (lixisenatide PI). The injection site (abdomen, thigh, or upper arm) does not significantly alter pharmacokinetics. Both exenatide formulations and lixisenatide are eliminated predominantly by glomerular filtration with subsequent proteolytic degradation. The mean terminal half-life of exenatide is 2.4 hours, with levels measurable up to 10 hours, thus allowing for

twice-daily dosing. The mean terminal half-life for lixisenatide is 3.5 hours. The metabolism and elimination are dose independent. ER exenatide is released from microspheres over ~10 weeks after administration. After discontinuation of therapy, minimal detectable concentrations can be seen in ~10 weeks.[244]

Absorption of liraglutide is delayed owing to its self-association in heptameric aggregates within the injection depot that are too large to cross the capillary membranes.[244,245] On disassociation of the heptamers at the absorption site, liraglutide is absorbed. This delayed absorption is the primary reason for its prolonged action. Liraglutide is highly protein bound (>98%), with a half-life of 13 hours, allowing for once-daily dosing.[244,245] Metabolism of liraglutide occurs endogenously in a manner similar to that of large proteins, and there is no specific organ as its route of elimination.[246]

Dulaglutide achieves maximum plasma concentration in about 48 hours, and steady state occurs between 2 and 4 weeks with once-weekly administration. There is no statistically significant difference of exposure to dulaglutide between the site of administration in the abdomen, upper arm, or thigh. Metabolism occurs through general protein catabolism pathways into its component amino acids. The elimination half-life is ~5 days.[247]

The SC once-weekly semaglutide formulation reaches maximum concentration 1 to 3 days after the first dose and is highly protein bound. The medication reaches steady state after 4 to 5 weeks of once-weekly administration. Both semaglutide oral and SC formulations are also metabolized after proteolytic cleavage, but β-oxidation is also required to break down the fatty acid sidechain. Semaglutide has a half-life of 1 week, and will stay in circulation for ~5 weeks after the last dose. The formulation of semaglutide to salcaprozate sodium allows the polypeptide chain to be absorbed more readily in the stomach while minimizing degradation from the acidic environment.

ADVERSE EFFECTS

GI side effects are common and dose dependent, particularly nausea, vomiting, and diarrhea. Rates vary between agents, with exenatide ER appearing to have the lowest rates in placebo-controlled trials.[242,243,245,246,248] These side effects may be lessened by starting patients on lower doses for daily injections, ensuring correct timing and administration of the drug, and titrating the dose slowly. Other reported side effects have included decreased appetite and injection site reactions. Hypoglycemic risk can be increased in patients who are also taking an oral insulin secretagogues (eg, sulfonylurea) or insulin.[242,243,245,246,248]

These agents have been rarely related to hypersensitivity reactions, acute pancreatitis, and reduced renal function. Patients should be educated about symptoms of acute pancreatitis, including severe abdominal pain accompanied by vomiting, and instructed to report to their practitioner immediately. Patients in whom acute pancreatitis is confirmed with no other probable cause should not be rechallenged with GLP-1 agonists.[242,243,245,246,248,249]

The development of antibodies against these agents is well established. In general, the presence of antibodies does not appear to significantly affect the A_{1c} reduction seen with GLP-1 agonists, although some patients with high antibody titers may experience reduced efficacy.[242,243,245,246,248] Patients who demonstrate adherence to therapy, yet experience no change or worsening in glycemic control, should discontinue therapy and be switched to alternative agents.

CONTRAINDICATIONS AND PRECAUTIONS

GLP-1 agonists are contraindicated in patients with known hypersensitivity. They should not be used in patients with a history of pancreatitis.[243,250] They are not recommended for use in patients with severe GI disease. Exenatide should not be used in severe renal impairment (CrCl <30 mL/minute) or end-stage renal failure, or in those requiring hemodialysis.[246,248] There is limited clinical experience using dulaglutide in patients with end-stage renal disease (ESRD) and should be used with caution in these patients. If these

patients experience GI adverse effects, renal function should be closely monitored.[242,243,245,246,248]

GLP-1 agonists are contraindicated in patients with a personal or family history of medullary thyroid carcinoma (MTC) or in patients with multiple endocrine neoplasia syndrome type 2 (MEN 2) because of risks in rodents. A causal relationship in humans has not been established.[242,243,245,246,248] Currently, the FDA has required black box warnings on each of the GLP-1 agonists for MTC, MEN 2, and thyroid cancer, as well as a REMS program for each medication.

DRUG INTERACTIONS

GLP-1 agonists may increase the risk of hypoglycemia when used with sulfonylureas or insulin. Because of their mechanism of action, they may reduce the rate and extent of absorption of orally administered drugs.[242] They should, therefore, be used with caution in patients taking medications that require rapid GI absorption and are dose dependent on threshold concentrations for efficacy, such as antibiotics and oral contraceptives. The manufacturers of twice-daily exenatide recommend that patients take the affected medications at least 1 hour before exenatide administration.[242,243] There have been case reports of an increased international normalized ratio, sometimes associated with bleeding, in patients taking exenatide and warfarin. Patients should be closely monitored, with dose adjustments to warfarin therapy made as needed.[242,243,246,251–254]

EFFICACY

In clinical trials, maximal doses of GLP-1 agonists combined with a sulfonylurea, metformin, a TZD, or sulfonylurea plus metformin therapy reduced FBG between by 5 and 41 mg/dL, 2-hour postprandial BG by 60 to 70 mg/dL. In patients with type 2 diabetes, A_{1c} was reduced by 0.7% to 1.9%, and body weight was reduced from 3.08 to 11.02 pounds (1.4–5 kg).[255]

CARDIOVASCULAR BENEFIT

The ADA guidelines recommend that patients with high ASCVD risk be placed on GLP-1 agonists (or SGLT-2 inhibitors) if extra glycemic control is needed past metformin. Four GLP-1 agonists on the market have shown to improve MACE: liraglutide, dulaglutide, semaglutide, and semaglutide oral. Liraglutide was shown to decrease MACE by 13%, CV death by 22%, and all-cause mortality by 15%.[256,257] SC semaglutide and dulaglutide were found to reduce MACE by 26% and 12%, respectively.[258] Oral semaglutide showed a 21% reduction in MACE and other statistically significant findings with all-cause mortality and hospitalization due to HF.[255–258] With this abundance of positive data, liraglutide, dulaglutide, and semaglutide have been FDA approved to reduce the risk of MACE in adults with type 2 DM and established CVD.[259]

RENAL BENEFIT

GLP-1 agonists are recommended in the ADA guidelines for patients with underlying renal insufficiency second only to SGLT-2 inhibitors. Comprehensive and well-powered renal studies with GLP-1 agonists have yet to be conducted; however, renal function has been monitored as secondary end points in CV trials. The urine albumin–creatinine ratio (UACR) favored lixisenatide (24% vs 34% placebo group, P = .004); however, there were similar median UACR at baseline and at follow-up.[255] Liraglutide was found to have a decrease in composite microvascular outcomes and a decrease in nephropathic events by 16% and 22%, respectively.[256] Semaglutide was observed to decrease new or worsening nephropathy by 36%.[257] Dulaglutide decreased renal outcomes by 15%.[257] Uniquely, patients on dulaglutide 1.5 and 0.75 mg were compared to patients on insulin glargine and were found to have higher eGFRs after 1 year, but no significantly different reduction in UACR.

DOSAGE AND CLINICAL USE

Exenatide (not the ER formulation) is approved for use as monotherapy, whereas the other GLP-1 agonists are not recommended as monotherapy per the manufacturers. GLP-1

agonists are indicated as add-on agents in patients with type 2 diabetes who have been unable to reach target goals on monotherapy with metformin or in combination therapy. Although not indicated for weight loss, these agents may be helpful in patients with type 2 diabetes who are obese and struggling with obesity. Exenatide has been studied in patients with type 2 diabetes already on insulin glargine; exenatide lowered the A_{1c} by 1.7% and patients required lower doses of insulin glargine compared with the placebo group.[242,243,245,246,248]

The starting dose of exenatide is 5 µg injected SC into the abdomen, thigh, or arm twice daily in the 60 minutes before morning and evening meals. Patients who experience severe GI side effects may try injecting just before meals initially, and then move from 30 to 60 minutes before meals. If a patient tolerates the 5-µg dose, then it can be titrated after 1 month of therapy to the maximal dose of 10 µg SC twice daily. The dose of ER exenatide is 2 mg given SC once weekly without regard to meals at any time of the day. The starting dose of liraglutide is 0.6 mg injected SC into the abdomen, thigh, or arm once daily for 1 week, and then it may be increased to 1.2 mg SC daily. If the A_{1c} goal is not achieved with a 1.2-mg dose, the dose can be further increased to 1.8 mg daily. The starting dose of dulaglutide is 0.75 mg injected SC into the abdomen, thigh, or upper arm once weekly given at any time of the day, and may be increased to 1.5 mg once weekly if adequate glycemic control is not achieved.[242,243,245,246,248]

When any of these agents are added to the treatment regimen of a patient who is also taking a sulfonylurea or glinide, the insulin secretagogue dose may need to be lowered (by about half) to reduce the risk of hypoglycemia. If used in combination with basal insulin, the insulin dose may need to be decreased.[250,254,260–262]

Dipeptidyl Peptidase-4 Inhibitors

Currently, four DPP-4 inhibitors are available in the United States: sitagliptin, saxagliptin, linagliptin, and alogliptin.[263]

MECHANISM OF ACTION

The DPP-4 inhibitors inhibit the degradation of GIP and GLP-1 on entering the GI vasculature, thus increasing the effects of these endogenous incretins on first-phase insulin secretion and glucagon inhibition.[260] They are all competitive inhibitors of DPP-4. Sitagliptin, at a 100-mg dose, reduces DPP-4 activity by 80% for up to 24 hours,[261] whereas saxagliptin, at a 2.5-mg dose, reduces DPP-4 activity by 50% for up to 24 hours.[262] Alogliptin, at a dose of at least 25 mg, has been shown to reduce DPP-4 activity by >80% at a dose of at least 25 mg for at least 24 hours.[250] Linagliptin, at the standard dose of 5 mg, has been shown to reduce DPP-4 activity by >80% for up to 24 hours.[264] In contrast to GLP agonists, which increase GLP-1 levels by 6- to 10-fold,[254] these agents not only modestly increase GLP-1 levels (two- to threefold) but also increase GIP levels. As a result, DPP-4 inhibitors have minimal to no effect on satiety and delaying gastric emptying.

PHARMACOKINETICS

Sitagliptin is rapidly absorbed, with an absolute bioavailability of 87%.[265] Absorption is unaffected by food. Peak plasma concentrations occur in 1 to 4 hours, and its terminal half-life is 12.4 hours. Only 38% of sitagliptin is plasma protein bound. Eighty-seven percent of the parent drug is excreted unchanged in the urine, primarily by active renal tubular secretion, and may involve P-glycoprotein (P-gp) and human organic anion transporter (OAT) 3. Metabolism by CYP3A4, and to a much lesser extent, CYP2C8, plays a minimal role in the excretion of metabolites in the feces.[260]

Saxagliptin is well absorbed, with a bioavailability estimated to be 75%.[266] Although food increases absorption by 27%, it can be administered with or without food. Peak plasma concentrations occur at 2 hours for saxagliptin and at 4 hours for the active metabolite. Saxagliptin is metabolized by CYP3A4/5 to a major metabolite that is one-half as potent.[265] Protein binding of saxagliptin and its active metabolite is negligible. The mean plasma terminal half-lives of saxagliptin and its active metabolite are 2.5 and 3.1 hours,

respectively. Saxagliptin is excreted primarily by the kidneys, with 25% excreted unchanged in the urine, and 36% of the active metabolite found in urine. Approximately 22% of drug and metabolite are excreted in feces.[250]

Linagliptin is well absorbed and has a bioavailability of 30%. A high-fat meal can decrease the absorption by 15%; however, this is not clinically significant. Therefore, linagliptin may be administered with or without food. Peak plasma concentrations occur at ~1.5 hours after a dose of 5 mg. Linagliptin has a long terminal half-life (>100 hours) because of the biphasic decline in plasma concentrations, which is related to the binding of DPP-4. Approximately 90% of linagliptin is excreted unchanged in the urine, and a small percentage is metabolized to an inactive metabolite.[262]

Alogliptin is well absorbed and has a bioavailability of 100%. A high-fat meal results in no significant change in absorption; therefore, it may be administered with or without food. Alogliptin is 20% plasma protein bound, with 60% to 71% of the dose excreted unchanged in urine and 13% excreted in the feces. Limited metabolism occurs via CYP2D6 and CYP3A4. The terminal half-life of alogliptin is ~21 hours after the administration of a 25-mg dose.[263]

ADVERSE EFFECTS

Because these agents differ significantly in chemical structure from one another, some adverse events may be unique to the individual agent, and may not be indicative of a class-wide effect.[254,262] The most commonly reported side effects with sitagliptin and alogliptin include nasopharyngitis, upper respiratory tract infection, hypoglycemia, and headache.[260,261] Saxagliptin can cause these same adverse effects, as well as urinary tract infection, whereas linagliptin adverse effects can include hypoglycemia, nasopharyngitis, diarrhea, and cough.[267] It is possible that DPP-4 inhibitors may have an effect on the immune system, because lymphocytes express DPP-4. These medications have been suggested to increase risk of pancreatitis; however, studies have shown this risk to be low.[268,269] DPP-IV inhibitors pose relatively low

risk for hypoglycemia, and are recommended for patients with a compelling need to reduce hypoglycemic episodes per ADA and AACE guidelines.

CONTRAINDICATIONS AND PRECAUTIONS

All DPP-4 inhibitors should be avoided in patients with a history of serious hypersensitivity reaction to the drug. The FDA released an alert in regard to saxagliptin and alogliptin in April 2016. These medications were found to increase the risk of HF, especially in patients with heart or kidney disease.[254]

DRUG INTERACTIONS

Sitagliptin is not significantly protein bound.[254,264] It also does not inhibit CYP isoenzymes or induce CYP3A4; therefore, it is not expected to interact with other drugs that are metabolized by these pathways. Patients taking digoxin, a substrate of P-gp–like sitagliptin, should be monitored for any signs or symptoms of digoxin toxicity, because a slight increase in the AUC (11%) and C_{max} (18%) has been observed.[260]

Saxagliptin does have significant drug interactions because it is metabolized by CYP3A4/5.[261] Therefore, if used with strong inhibitors of these enzymes (eg, ketoconazole, itraconazole, clarithromycin, telithromycin, and protease inhibitors such as indinavir), the dose of saxagliptin is reduced to 2.5 mg daily.

Linagliptin is a weak-to-moderate inhibitor of CYP3A4 and a P-gp substrate, and inhibits P-gp–mediated transport of digoxin at high concentrations.[262] Medications that are strong inducers of CYP3A4 or P-gp, such as rifampin, decrease linagliptin to levels that are subtherapeutic and ineffective; therefore, if treatment with those medications is necessary, an alternative to linagliptin should be used.

Alogliptin is not significantly protein bound, and metabolism through the cytochrome P450 pathway is negligible; therefore, there are no significant drug interactions with alogliptin.[254]

EFFICACY

In monotherapy clinical trials versus placebo, sitagliptin lowers fasting glucose by 12 mg/dL and A_{1c} by 0.5% to 0.6% compared with baseline (0.6%–0.8% compared with placebo)[260]; saxagliptin is comparable, with A_{1c} lowering by 0.5% (0.6% vs placebo) and FPG by 15 mg/dL.[254,260,264] In addition, both agents reduce 2-hour postprandial glucose by ~45 mg/dL.[261] When used as add-on combination therapy, A_{1c} lowering is greater (0.7%–0.9%). Linagliptin, as monotherapy in clinical trials versus placebo, decreased fasting glucose by 13 mg/dL from baseline and A_{1c} by 0.4%.[262] Alogliptin, as monotherapy in clinical trials versus placebo, decreased fasting glucose by 16 mg/dL and A_{1c} by 0.6%.[264] Unlike the GLP-1 mimetics and analogs, DPP-4 inhibitors do not significantly affect body weight, appetite, or satiety, and are considered weight neutral.[268–271] As is the case for the GLP-1 mimetics and analogs, further studies are needed to more clearly determine the effects of DDP-4 inhibitors on long-term preservation of β-cell function.

CARDIOVASCULAR BENEFIT

Several clinical studies were conducted to determine the impact of DPP-IV inhibitors on CV health. When compared with placebo saxagliptin, alogliptin, sitagliptin, and linagliptin had no statistically significant difference in reduction of CV death, nonfatal MI, nonfatal stroke, or hospitalization for unstable angina,[272] Linagliptin was also compared to glimepiride, a sulfonylurea, and was found to be noninferior for MACE.[269]

RENAL BENEFIT

Limited data exist with DPP-IV inhibitors and long-term renal impact. Post hoc analyses were conducted on CV trials involving saxagliptin, alogliptin, and sitagliptin. Saxagliptin was shown to have reduced development and progression of microalbuminuria[268,270]; however, alogliptin and sitagliptin demonstrated no significant differences in

renal outcomes between groups.[254] In the CV trial for linagliptin, renal findings were recorded as secondary outcomes. No differences were found between linagliptin and placebo.

DOSAGE AND CLINICAL USE

DPP-4 inhibitors are mainly used as add-on therapy in combination with other agents. However, all are approved for use as monotherapy. Sitagliptin may be initiated at 100 mg taken once daily with or without food.[260] Renal function should be assessed before initiation of this agent. In patients with moderate renal insufficiency (CrCl 30–50 mL/minute), the dose for sitagliptin should be reduced to 50 mg once daily, and in severe renal insufficiency (CrCl <30 mL/minute) or for those in end-stage renal failure requiring dialysis, the sitagliptin dose is 25 mg once daily. Sitagliptin may be administered without regard to the timing of hemodialysis. Only sitagliptin should be used in patients on peritoneal dialysis.

Saxagliptin is dosed at 2.5 to 5 mg once daily with or without food.[261] Renal function should be assessed before initiation of this agent. In patients with moderate or severe renal impairment or ESRD with a CrCl < 50 mL/minute, the recommended dose is 2.5 mg daily. If patients are taking strong CYP3A4/5 inhibitors, the dose of saxagliptin should be 2.5 mg daily. In patients on hemodialysis, the dose is 2.5 mg daily to be administered after hemodialysis.

Linagliptin is dosed at 5 mg once daily with or without food. No dose adjustment is necessary for patients with renal impairment; however, patients with a CrCl <30 mL/minute may be more prone to hypoglycemia; therefore, dosing adjustments of concomitant antidiabetic medications and frequent monitoring may be necessary.[262]

Alogliptin is dosed at 25 mg once daily with or without food. Renal function should be assessed before initiation of this medication. In patients with moderate renal impairment with a CrCl of 30 to 60 mL/minute, the recommended dose is 12.5 mg once daily. In patients with severe renal impairment (CrCl <30 mL/minute) or ESRD, the dose is 6.25 mg once daily. Patients on hemodialysis should be

given 6.25 mg once daily, and it may be administered without regard to the timing of dialysis.[273]

When any of these agents are added on for a patient also on a sulfonylurea or glinide, the insulin secretagogue dose may need to be lowered (by about half) to reduce the risk of hypoglycemia. Similarly, when sitagliptin is added on for a patient already on insulin therapy, the dose(s) of insulin may need to be lowered initially and then readjusted depending on the response to sitagliptin.

Amylin Receptor Agonists (Amylinomimetics)

MECHANISM OF ACTION

Amylin is a hormone found in the β cells where it is comanufactured, stored, and released with insulin in response to food intake.[274] Its actions seem to be centrally mediated and include slowing gastric emptying, suppressing glucagon secretion, and modulating the regulation of appetite. Amylin is absent in patients with type 1 diabetes. In patients with type 2 diabetes, its concentrations are altered to mirror those of insulin at different points in the progression of the disease. Pramlintide, a synthetic amylin analog, is available in the United States for the adjunctive treatment of patients with both type 1 and type 2 diabetes who use mealtime insulin.

PHARMACOKINETICS

The absolute bioavailability of SC injected pramlintide is 30% to 40%.[274] SC injection into the abdomen and thigh allows for more predictable absorption and distribution than when administered into the arm. Approximately 40% of the drug is unbound in plasma. The half-life is about 48 minutes, and time to maximum concentration is ~20 minutes. Pramlintide is metabolized by the kidneys to an active metabolite with a half-life similar to the parent drug.

ADVERSE EFFECTS

GI symptoms—including mild-to-moderate nausea (28%–48%), vomiting (8%–11%), and anorexia (9%–17%)—are the most

frequently reported adverse reactions associated with therapy.[274] GI symptoms are usually transient, subsiding after 4 to 8 weeks of treatment or with dose reduction and slow dose escalation. Hypoglycemia can occur in up to 16.8% of patients with type 1 diabetes receiving pramlintide and insulin therapy, and in 8.2% of patients with type 2 diabetes receiving pramlintide and insulin.

CONTRAINDICATIONS AND PRECAUTIONS

Pramlintide is contraindicated in patients with known cresol hypersensitivity, hypoglycemic unawareness, and gastroparesis.[274] Severe hypoglycemia can occur when it is used in combination with insulin and medications that can slow gastric emptying. Amylin mimetics are not recommended for use in patients with poor adherence to insulin regimen or in patients who have difficulty taking BG levels routinely. This agent should also be avoided in patients with an A_{1c} >9%. Drugs that can alter glucose metabolism when administered with pramlintide, and therefore cause hypoglycemia, include oral antidiabetics, fibrates, fluoxetine, salicylates, and angiotensin-converting enzyme inhibitors (ACEIs), and should be used with caution if administered concomitantly. Pramlintide has a black box warning for severe hypoglycemia, which can occur within 3 hours of an injection of pramlintide. Caution individuals while driving, those who operate heavy machinery, and those who engage in other high-risk activities because of potential serious injuries that may result during a hypoglycemic episode.

DRUG INTERACTIONS

As noted, severe hypoglycemia can occur in patients who are concurrently taking an oral hypoglycemic agent (eg, sulfonylurea) or insulin (see following section on Dosage and Clinical Use).[274] Because pramlintide can delay the absorption of medications that are administered concomitantly, medications that require rapid onset for effectiveness, such as antibiotics, oral contraceptives, and analgesics, should be administered at least 2 hours after or 1 hour before the pramlintide injection.

EFFICACY

In clinical studies of patients with type 2 diabetes with doses up to 150 µg/day for 52 weeks, pramlintide combined with insulin decreased A_{1c} by 0.3% and weight by 5.66 pounds (2.57 kg).[72] Clinical studies of patients with type 1 diabetes taking insulin in combination with pramlintide or placebo demonstrated A_{1c} reductions of 0.2% to 0.4% and weight loss of 0.88 to 2.87 pounds (0.4–1.3 kg).[274]

DOSAGE AND CLINICAL USE

In clinical practice, pramlintide is considered an add-on agent primarily for patients with type 1 diabetes who have failed to achieve target BG goals on insulin therapy alone. Its practical use is more limited to obese patients with type 2 diabetes who have failed to achieve target BG levels with a regimen that includes a sulfonylurea or insulin. Pramlintide is available in a pen device (SymlinPen®). It cannot be mixed with any type of insulin. The pens (60 pen-injector for 15-, 30-, 45-, or 60-µg doses and 120 pen-injector for 60- and 120-µg doses) in use may be stored at room temperature (86 °F [30 °C]) for up to 30 days.[274]

For patients with type 1 diabetes, the initial dose is 15 µg, and for patients with type 2 diabetes, the initial dose is 60 µg. Pramlintide is injected SC into the abdomen or thigh immediately before every major meal. A major meal is one that contains ≥30 g of carbohydrate or ≥250 kcal. If a meal is skipped, the pramlintide dose should be skipped. When initiating pramlintide therapy, the dose of premeal insulins must be reduced by at least 50%. Patients should be closely followed up and instructed to intensively monitor and record BG (fasting, preprandial, and postprandial) levels and any hypoglycemic episodes until control has stabilized. Pramlintide is titrated based on achieving optimal glucose control with minimal side effects (eg, nausea). The dose can be increased when no clinically significant nausea has occurred for 3 to 7 days. For patients with type 1 diabetes, doses may be increased in 15-µg increments up to a

maximum meal dose of 60 µg. For patients with type 2 diabetes, the dose may be increased to 120 µg before every major meal.[275–277]

Sodium–Glucose Transporter 2 Inhibitors

SGLT-2 inhibitors reduce BG by decreasing tubular reabsorption of glucose in the kidney, thereby increasing the excretion of urinary glucose.[275–277] These agents are highly selective, reversible inhibitors of SGLT-2. Currently, there are four agents in this class: canagliflozin, dapagliflozin, empagliflozin, and ertugliflozin, which are available as individual agents or in combination with various other antidiabetic agents.[278] Because their mechanism of action is independent of insulin resistance or β-cell function, these medications can be used in combination with all antidiabetic agent classes, including insulin, for the treatment of type 2 DM in addition to diet and exercise. These agents have added benefits of weight loss, increase in HDL, and decrease in BP; however, they are associated with an increased risk of genital and urinary infections.[279–285] SGLT-2 inhibitors have become a preferred agent in patients with CKD and HF.[62] Per the ADA guidelines, these versatile agents are also recommended as a treatment option for patients with ASCVD, high ASCVD risk, hypoglycemic risk, or with a need to reduce weight. In addition, they are a preferred first choice for patients with CKD and HF.[286] SGLT-2 inhibitors have been studied in patients with type 1 diabetes with positive effects on glycemic control; however, these agents increased the risk of DKA significantly, and are therefore not recommended for this patient population.[275]

PHARMACOKINETICS

Canagliflozin has a bioavailability of 65%, and peak plasma concentrations occur within 1 to 2 hours of the dose being administered.[276] There was no effect on absorption when administered with a high-fat meal; therefore, canagliflozin may be administered with or without food. Canagliflozin is 99% protein bound, primarily to albumin. This agent is metabolized primarily by

glucuronidation by UGT1A9 and UGT2B4 to two inactive metabolites. Approximately 7% is metabolized by CYP3A4. Approximately 33% of a dose is excreted in the urine as metabolites, and <1% is excreted as unchanged canagliflozin in the urine. The terminal half-life is 10.6 hours for a 100-mg dose and 13.1 hours for a 300-mg dose.

Dapagliflozin has a bioavailability of 78% after the administration of a 10-mg dose.[277] The C_{max} occurs at ~2 hours under fasting state. Taking dapagliflozin with a high-fat meal decreases the C_{max} by up to 50%; however, this change is not clinically significant. Therefore, it may be administered with or without food. Dapagliflozin is ~91% protein bound, and is metabolized primarily by the UGT1A9 pathway and to a small extent by CYP 3A4 to yield inactive metabolites. This agent and the inactive metabolites are excreted 75% in the urine and 21% in the feces, with 15% being excreted as unchanged drug. The terminal half-life is ~12.9 hours following a single-dose administration.

Empagliflozin reached peak plasma concentrations at 1.5 hours postoral administration.[275] Plasma concentrations then declined in a biphasic manner, with a rapid distribution phase and a slower terminal phase. The C_{max} decreased by 37% after administration with a high-fat meal; however, this was determined to be clinically insignificant. Therefore, empagliflozin may be administered with or without food. Empagliflozin is 86.2% bound to plasma proteins, and the agent is primarily metabolized by glucuronidation by UGT3B7, UGT1A3, UGT1A8, and UGT1A9. No major metabolites were detected in plasma. Approximately 41.2% of the drug was eliminated in feces (unchanged parent drug), whereas 54.4% was eliminated in urine (half is unchanged parent drug). The terminal half-life is ~12.4 hours.

ADVERSE EFFECTS

In clinical trials, SGLT-2 inhibitors commonly reported adverse effects that include female genital mycotic infections, increased urination, and urinary tract infections[287]; with an overall incidence of

4% to 6%.[275–277,288] Another common adverse effect associated with SGLT-2 inhibitors includes nasopharyngitis.[275–277]

CONTRAINDICATIONS AND PRECAUTIONS

All SGLT-2 agents are contraindicated in patients with hypersensitivity reactions to the agents and in patients with severe renal impairment, ESRD, and dialysis.[278] Although these agents have proven benefit in patients with CKD, they are not recommended in patients with severe renal impairment and would place these patients at increased risk for renal adverse effects. Renal function should be assessed before the initiation of these agents and periodically during treatment. BP should be assessed in patients before initiation with these agents, and hypovolemia should be corrected because of the potential of these agents to lower BP, especially in patients already taking antihypertensive medications. Hypoglycemia may occur when SGLT-2 agents are used in combination with insulin and secretagogues; therefore, the doses of the concomitant agents may need to be decreased. Renal function may be impaired with use of these agents; therefore, renal function monitoring should occur during therapy. Serum concentrations of LDL may be increased with SGLT-2 therapy, which may require medication therapy, and serum LDL concentrations should be monitored. In clinical trials, dapagliflozin has shown an increase in bladder cancer cases as compared to placebo; therefore, patients with previous history of bladder cancer should not take dapagliflozin.[289]

In May 2015, the FDA released a Drug Safety Communication warning that SGLT-2 agents may cause ketoacidosis and that patients should be warned to seek medical attention if they experience signs and symptoms of ketoacidosis including confusion, fatigue, difficulty breathing, abdominal pain, nausea, or vomiting.[290] The cases were not typical of DKA cases, because blood sugars were not highly elevated. In some of the cases, DKA may have been triggered by major illness. The FDA will monitor the safety of these

agents and determine whether prescribing information changes are warranted.

As of 2015, the FDA strengthened a precaution regarding canagliflozin as evidence surrounding low bone mineral density and increased risk of bone fractures emerged. Conversely, the FDA rescinded a precaution involving canagliflozin and increased risk of foot amputations in 2020.[275]

DRUG INTERACTIONS

Canagliflozin weakly inhibits CYP2B6, CYP2C8, CYP2C9, and CYP3A4, is a weak inhibitor of P-gp, and is a substrate of drug transporters P-gp and multidrug resistance–associated protein 2 (MRP2).[276] Rifampin decreases the efficacy of canagliflozin; therefore, the dose of canagliflozin may need to be increased. When administered concomitantly with digoxin, there was an increase in the AUC (20%) and C_{max} (36%) of digoxin; therefore, digoxin should be monitored appropriately.

Dapagliflozin does not inhibit CYP enzymes and is a weak substrate of the P-gp active transporter. The dapagliflozin metabolite is a substrate for the OAT3 active transporter; however, it did not inhibit P-gp, OCT2, OAT1, or OAT3 active transporters with any clinical significance. Therefore, dapagliflozin is unlikely to affect the pharmacokinetics of concurrently administered medications that are substrates of these enzymes. Coadministration of dapagliflozin with rifampin, a nonselective inducer of UGT1A9, may cause a decrease in dapagliflozin serum concentrations, which may lead to a decrease in dapagliflozin efficacy.[277]

Empagliflozin does not induce or inhibit CYP450 enzymes or UGT1A1; therefore, it is not expected to have interactions with concomitantly administered medications that are substrates of the CYP450 pathway or UGT1A1.[276]

EFFICACY

Canagliflozin monotherapy versus placebo decreased A_{1c} by 0.77% to 1.03%, decreased FPG by 27 to 35 mg/dL, and decreased body

weight by 2.8% to 3.9%.[276] In a clinical trial comparing dapagliflozin monotherapy to placebo, A_{1c} was decreased by 0.8% to 0.9% and FPG was decreased by 24.1 to 28.8 mg/dL.[277] Empagliflozin monotherapy, in a clinical trial compared to placebo, decreased A_{1c} by 0.7% to 0.8%, decreased FPG by 19 to 25 mg/dL, and decreased body weight by 2.8% to 3.2%.[279]

CARDIOVASCULAR EFFECTS

Several SGLT-2 inhibitors have shown significant reductions in CV events when compared with placebo. Empagliflozin showed a 32% reduction in all-cause mortality and a 38% reduction in CV death.[277] As a result, the FDA approved empagliflozin for another indication: prevention of death from CVD in adults with type 2 diabetes and existing CVD.[281] Canagliflozin demonstrated a 14% reduction in MACE,[283] and dapagliflozin showed a 17% reduction in CV death or hospitalization for HF as a composite end point[291] when compared with placebo. Ertugliflozin has not demonstrated a statistically significant reduction in CV death, MI, or stroke.[280]

HEART FAILURE EFFECTS

The current body of evidence suggests that SGLT-2 inhibitors have significant benefit in patients with heart failure with reduced ejection fraction (HFrEF). Empagliflozin showed a 25% reduction in the composite end point of HF hospitalization and CV death regardless of type 2 diabetes status and a 30% reduction in HF hospitalization.[285] The study involving dapagliflozin indicated a 26% reduction in worsening HF or CV mortality and a 25% reduction in CV death and HF hospitalization.[281] This data prompted the FDA to give dapagliflozin a new indication for patients with HFrEF. Canagliflozin was found to have a 22% composite reduction in HF hospitalization and CV death and an overall 33% reduction in HF hospitalization.[291] Ertugliflozin was also found to reduce the risk of HF-related hospitalizations with a number needed to treat (NNT) of ~29 patients.[292] In 2021, empagliflozin was found to significantly reduce the risk of the composite CV death or hospitalization for HF in

adults, with or without diabetes, in patients with HF with preserved ejection fraction (HFpEF).[279] Dapagliflozin is currently still being studied for patients with HFpEF.

RENAL EFFECTS

SGLT-2 inhibitors operate within the kidney, and were thus postulated to affect the nephropathic nature of type 2 diabetes. Empagliflozin was shown to have a 39% reduction in development of nephropathy when compared with placebo.[282] The trials investigating the renal outcomes involving canagliflozin and dapagliflozin were both stopped early because of overwhelmingly positive effects. Canagliflozin demonstrated a 30% reduction in the composite end point of ESRD, a doubling of SCr, or death from renal or CV causes.[284] Dapagliflozin showed a 39% reduction in the risk of declining kidney function, onset of ESRD, or death from renal failure even in patients without diabetes.[291] As of 2021, dapagliflozin was given an added indication for patients with CKD (with or without diabetes) to help reduce the risk of kidney function decline, kidney failure, CV death, and hospitalization due to HF. A secondary end point of ertugliflozin in the CV trial—a sustained 40% in eGFR, dialysis/transplant, or renal death—was 34% lower in the ertugliflozin group than when compared with placebo.[293]

DOSAGE AND CLINICAL USE

The SGLT2 agents are indicated for use in patients with type 2 DM as an adjunct to diet and exercise as monotherapy or concomitantly with other antidiabetic agents. The initial dose of canagliflozin is 100 mg once daily taken before the first meal of the day, and can be increased to 300 mg once daily in patients who need additional glycemic control and have an eGFR >60 mL/minute/1.73 m^2.[275] In patients with an eGFR of 30 to 60 mL/minute/1.73 m^2, the dose is limited to 100 mg once daily, and should be discontinued in patients with an eGFR <30 mL/minute/1.73 m^2.[276] Dapagliflozin should be initiated at a dose of 5 mg once daily in the morning, with or without food, and the dose may be increased in patients who need additional

glycemic control.[277] Monitor renal function before initiation, and do not use in patients with an eGFR <30 mL/minute/1.73 m^2. Empagliflozin should be initiated at a dose of 10 mg once daily in the morning, with or without food, and may be increased to 25 mg once daily.[277] Empagliflozin is not recommended for use to improve glycemic control in adults with type 2 diabetes with an eGFR <30 mL/minute/1.73 m^2.[288] Ertugliflozin should be initiated at 5 mg once daily and increased to 15 mg if tolerated and extra glycemic control is needed. Continued use is not recommended in patients with an eGFR between 30 and 45 mL/minute/1.73 m^2. Use is not recommended in patients with an eGFR <30 mL/minute/1.73 m^2.[294]

Other Agents

COLESEVELAM

In January 2008, the FDA approved a new indication for colesevelam (Welchol®), a bile acid sequestrant, to be used as add-on therapy in type 2 diabetes as an adjunct to diet and exercise.[294–297] The mechanism by which colesevelam reduces glucose is not known. It is a hydrophilic, water-insoluble polymer that is not absorbed. Therefore, its distribution is limited to the GI tract.[295–297] The primary side effects of colesevelam are GI (constipation, nausea, and dyspepsia). The following are contraindications for use of colesevelam:

- Patients with triglyceride levels of >500 mg/dL
- Patients with a history of bowel obstruction
- Patients with a history of pancreatitis caused by hypertriglyceridemia
- Patients with type 1 diabetes or for the treatment of DKA

Because of its constipating effects, it should not be used in patients with gastroparesis, other GI motility disorders, or in those who have had major GI tract surgery and may be at risk for bowel obstruction. The tablets are large and can cause dysphagia or esophageal obstruction; therefore, it should be used with caution in

patients with dysphagia or swallowing disorders. It should be used with caution in patients with triglycerides in excess of 300 mg/dL because bile acid sequestrants can cause concentrations of serum triglycerides to increase.[294]

Drug interactions are an important consideration for colesevelam because it reduces GI absorption of some drugs. Drugs with a known interaction with colesevelam (eg, phenytoin, warfarin, levothyroxine, and oral contraceptives) should be administered at least 4 hours before colesevelam. The bioavailability of glimepiride, glyburide, and glipizide may be affected by concomitant administration of colesevelam; therefore, these medications should be administered 4 hours before colesevelam.[298]

A_{1c} reductions associated with colesevelam are 0.3% to 0.4% compared with baseline (0.5% vs placebo). Colesevelam also reduces LDL-C by 12% to 16% when used in combination with metformin or a sulfonylurea, respectively.[294–297] Bile acid sequestrants can increase triglycerides by 5% to 22% in patients with type 2 diabetes, depending on which antidiabetic medications are given concomitantly.[294] Colesevelam is approved for use as combination therapy with metformin, a sulfonylurea, and insulin.[299] It has not been studied as monotherapy or in combination with DPP-4 inhibitors. It can provide an added benefit in patients with dyslipidemia. The dose is six (625 mg) tablets once daily or three tablets twice daily taken with a meal and liquid. Alternatively, a 3.75-g packet (powder for oral suspension) once daily or 1.875-g packet twice daily may be used by dissolving each dose in 4 to 8 ounces of water, fruit juice, or diet soda, and administering with a meal. Since its approval, its use for treatment of type 2 diabetes remains quite limited.

BROMOCRIPTINE

Bromocriptine mesylate, an ergot derivative, is a dopamine-2 receptor agonist that is a quick-release formulation.[293] It was FDA approved in May 2009 for use in type 2 diabetes. Bromocriptine has been available since 1978 and was once widely used for Parkinson

disease. The mechanism by which bromocriptine improves glycemic control is not known. A normal circadian peak in the central dopaminergic tone occurs in the early morning, and has been linked to induction of normal insulin sensitivity and glucose metabolism.[299] It is theorized that taking bromocriptine in the morning will increase central dopaminergic tone and reset the normal circadian rhythm to that of leaner people. The recommended dose of bromocriptine in diabetes is initiation with 0.8 mg daily, increasing by one tablet weekly until the maximum tolerated dose of 1.6 to 4.8 mg is reached. Bromocriptine is administered once daily within 2 hours of waking in the morning.[299] It should be taken with food to help reduce GI side effects such as nausea. Its effect on A_{1c} lowering is very mild: As monotherapy, A_{1c} is lowered by 0.1% compared with baseline (0.4% vs placebo), and as add-on therapy to a sulfonylurea or metformin, A_{1c} is reduced by 0.5%.[299] Common side effects include hypotension, dizziness, syncope, nausea, somnolence, headache, and exacerbation of psychotic disorders. Bromocriptine is contraindicated in patients with known hypersensitivity to ergot-related drugs, patients with syncopal migraine, and females who are nursing.[299] Bromocriptine is highly protein bound, and when given concomitantly with other drugs that are highly protein bound, such as sulfonamides, salicylates, and probenecid, the unbound fraction of these other drugs may increase, altering their risk of adverse effects or their effectiveness. Bromocriptine is metabolized by CYP3A4; therefore, caution should be used when administering concomitant drugs that are CYP3A4 substrates, inducers, or inhibitors. Neuroleptic agents with dopamine receptor agonist properties, such as olanzapine, clozapine, and ziprasidone, may reduce the effectiveness of both bromocriptine and the other drugs; therefore, concomitant use is not recommended. Given the minor A_{1c} lowering, bromocriptine quick release has a very limited role as a therapeutic agent.[63]

TREATMENT OF PATIENTS WITH TYPE 2 DIABETES

Clinical Presentation

CASE 53-11

QUESTION 1: L.H. is a 45-year-old, overweight, Mexican American female with central obesity (height, 65 inches [165.10 cm]; weight, 165 pounds [74.84 kg]; and BMI, 27.5 kg/m^2). Three months ago, she was referred to the diabetes clinic when her gynecologist, who had been treating her for recurrent monilial infections, noted glucosuria on routine urinalysis. Subsequently, on two separate occasions, she was found to have an FPG of 150 and 167 mg/dL; A_{1c} was also checked, and it was 8.2%. L.H. denies any symptoms of polyphagia or polyuria, although lately she has been more thirsty than usual. She does report symptoms of lethargy and takes afternoon naps when she can.

L.H.'s other medical problems include hypertension, which is well controlled on lisinopril 20 mg/day, and recurrent monilial infections, which are treated with fluconazole. She has given birth to four children (birth weights, 7 [3.18], 8.5 [3.69], 10 [4.54], and 11 pounds [4.99 kg]), and was told during her last pregnancy that she had "borderline diabetes." She currently works as a loan officer in a local bank and spends her weekends "catching up on her sleep" and reading. L.H. has been smoking one pack of cigarettes per day for 20 years and drinks an occasional glass of wine. She drinks at least two regular sodas daily and has a "large" glass of orange juice every morning. Her physical activity consists of routine walking during the day (eg, to her car). Her family history is significant for a sister, aunt, and grandmother with type 2 diabetes; all have "weight problems." L.H.'s mother is alive and well at age 77; her father died of a heart attack at age 47.

On presentation, fasting laboratory assessment reveals glucose of 147 mg/dL, triglycerides of 400 mg/dL, and an A_{1c} of 8.3% (normal, <5.7%).[26] All other values (including the complete blood count, electrolytes, LFTs, and renal function tests) are within normal limits. L.H. is given the diagnosis of type 2 diabetes.

What features in L.H.'s history and physical examination are consistent with this diagnosis?

The features of L.H.'s history that are consistent with type 2 diabetes include an FPG concentration of ≥126 mg/dL on more than

one occasion, an A_{1c} of ≥6.5%, high BMI with central obesity, age older than 40, physical inactivity, family history of diabetes, and Mexican American descent. L.H. also has delivered large babies, which suggests that she may have had undiagnosed gestational diabetes, a condition that places females at high risk for subsequently developing type 2 diabetes. Diagnosis on routine examination and mild signs and symptoms of hyperglycemia (including increased thirst and lethargy), recurrent monilial infections, hypertriglyceridemia, and indications of CVD (hypertension) also are typical in patients with type 2 diabetes (see section on Type 2 Diabetes and Table 53-1).

Treatment Goals

Case 53-11, Question 2: What should the goals of therapy be for L.H. and other patients with type 2 diabetes? Which biochemical indices should be monitored?

The beginning of this chapter discussed general goals of therapy for all people with diabetes, which include eliminating acute symptoms of hyperglycemia, avoiding hypoglycemia, reducing CV risk factors, and preventing or slowing the progression of both microvascular and macrovascular diabetic complications. The ADA recommends that otherwise healthy patients with type 2 diabetes strive to achieve the same biochemical goals as those recommended for people with type 1 diabetes (Tables 53-4 and 53-5).[62] When determining treatment goals for L.H. and others with type 2 diabetes, the same individual characteristics should be considered as for type 1 diabetes, such as the patient's capacity to understand and carry out the treatment regimen and the patient's risk for severe hypoglycemia. Given the data from the ACCORD, ADVANCE, and VADT trials, patients with type 2 diabetes and CVD or multiple CVD risk factors should be carefully assessed when determining their glycemic goals. For example, less aggressive A_{1c} goals should be considered for patients with advanced age (and short life

expectancy), longer duration of diabetes (>10 years), advanced microvascular complications, comorbid conditions such as significant cerebrovascular or coronary artery disease (because of the serious consequences related to hypoglycemia) or patients with long-standing diabetes in whom the goal is difficult to achieve despite diabetes self-management education, appropriate glucose monitoring, and effective doses of multiple antihyperglycemic agents including insulin.[39,47,300] Therefore, glycemic goals for patients with type 2 diabetes must be individualized. Emphasis should be placed on assessment of *all* CV risk factors, including hypertension, tobacco use, dyslipidemia, and family history.

As presented earlier in the section on Relationship of Glycemic Control to Microvascular and Macrovascular Disease, the UKPDS was a landmark study in patients with type 2 diabetes that conclusively demonstrated that improved BG control reduces the risk of developing retinopathy, nephropathy, and, potentially, neuropathy.[37] The 10-year follow-up study demonstrated that these outcomes persist even though the conventional group achieved similar glycemic control with time; an overall relative risk reduction in microvascular complications (24%) in the sulfonylurea- or insulin-treated group compared with patients who initially received conventional therapy was seen.[301–303] The exciting finding was that reductions in macrovascular complications emerged with time, with significant reductions in MI (15%) and death of any cause (13%) in patients initially intensively treated with sulfonylurea or insulin. Metformin appeared to be of particular benefit, with even greater reductions in MI and death of any cause (33% and 27%, respectively).

An additional finding of the UKPDS was that aggressive control of BP also significantly reduced microvascular complications, stroke, diabetes-related deaths, HF, and vision loss; during the 10-year follow-up study, these benefits diminished with time as the BP difference between the two groups was lost (ie, BP increased in the tight control group and decreased in the conventional group).[5] These findings emphasize the significance of maintaining BP control to reduce the risk of long-term complications.

Because L.H. is relatively young and has no symptoms of microvascular disease or neuropathy, every effort should be made to normalize her glucose concentrations to prevent these complications from occurring. Furthermore, a lipid panel should be ordered, and steps should be taken to achieve normal LDL-C, HDL-C, and triglyceride levels. Regardless of her current LDL level, L.H. should be initiated on at least a moderate-intensity statin therapy for CV risk reduction based on her age (between 40 and 75 years old).[5] A high-intensity statin would alternatively be recommended in patients considered to be at a higher CV risk (patients with multiple ASCVD risk factors or age 50–70 years) regardless of initial LDL cholesterol levels.[26] Often, triglyceride levels improve as BG concentrations decline and the metabolic response to insulin improves. (Management of dyslipidemia is addressed more fully later in this chapter.)

Biochemical indices that should be followed to monitor L.H.'s response to therapy include fasting, postprandial, and preprandial BG concentrations; A_{1c} values; and fasting triglyceride levels, as well as LDL-C and HDL-C concentrations. Based on ADA guidelines, initial metabolic goals for L.H. should be an A_{1c} value of <7%, an FPG of 80 to 130 mg/dL, and postprandial glucose concentrations <180 mg/dL.[26]

Treatment

LIFESTYLE INTERVENTIONS AND INITIAL THERAPY WITH METFORMIN

CASE 53-11, QUESTION 3: How should L.H. be managed initially?

Initial therapy for type 2 diabetes is aimed at lifestyle changes that will minimize insulin resistance and risk of CVD. In L.H.'s case and in the case of other overweight (BMI, 25.0–29.9 kg/m^2) or obese (BMI ≥30.0 kg/m^2) individuals with type 2 diabetes, this includes a lower calorie, low-fat, low-cholesterol diet; regular exercise; smoking

cessation (see Chapter 91, Tobacco Use and Dependence); and aggressive management of dyslipidemia and hypertension. Because central obesity is associated with increased insulin resistance, L.H. should be strongly encouraged to decrease her caloric intake, start exercising, and lose weight. Simple changes in her diet (such as cutting out juice and regular soda) and physical activity level can have a large impact on her glucose control. SMBG monitoring should be encouraged, and education that addresses the serious nature of DM and its long-term consequences also should begin. This is discussed in the previous sections on Medical Nutrition Therapy and Physical Activity, under Treatment (see also Table 53-14).

Initial pharmacologic therapy with metformin

The ADA recommends that most patients diagnosed with type 2 diabetes begin therapy with lifestyle modifications, including those mentioned earlier. In addition, most patients should begin monotherapy with metformin upon diagnosis. If metformin is contraindicated or poorly tolerated, an alternative agent approved for monotherapy may be used.[300] In the case that L.H. could not tolerate metformin, it may be beneficial to select an SGLT-2 inhibitor or a GLP-1 agonist to help reduce A_{1c} and help with comorbidities such as obesity. The selection of alternative agents is discussed later in this chapter. Although the UKPDS demonstrated that intensive therapy with sulfonylureas, metformin, and insulin reduces glucose with equal effectiveness (TZDs, DPP-IV inhibitors, SGLT-2 inhibitors, and GLP-1 agonists were not studied), metformin is favored as a first-choice agent in type 2 diabetes, particularly in overweight patients. This is because metformin lowers BG by decreasing hepatic glucose output and insulin resistance (indirectly) without causing weight gain or hypoglycemia. Metformin also has beneficial effects on plasma lipid concentrations, as well owing to a reduction in LDL and fatty acids.[37]

Another reason for metformin being a first choice for initial therapy is not only its proven benefit to reduce risk of microvascular complications but also macrovascular disease and mortality.[298]

Furthermore, in an observational study of patients with type 2 diabetes, and established coronary artery disease, cerebrovascular disease, or peripheral arterial disease, metformin use was associated with a significant reduction in all-cause mortality (22%) after only 2 years of follow-up.[304] Metformin is also emerging as a therapy that may reduce cancer risk, possibly attributable to its activation of AMPK, which can suppress tumor formation. Data so far have been in animal models and observational studies in humans.[305]

A drawback to immediate-release metformin is that it requires multiple daily dosing, and its dose also must be titrated to minimize GI effects. After the dose is established, it is possible to use a long-acting product that can be dosed once daily. Alternatively, ER metformin may be initiated at a dose of 500 mg daily and titrated upward as tolerated. The ER formulation may be preferred in many patients owing to the overall decreased risk of GI adverse effects associated with this formulation. One study revealed that any GI ADR was decreased by ~15% and diarrhea was reduced by ~10% after switching to ER formulation.[306] Renal function tests should be evaluated before the drug is initiated. L.H. does not have any contraindications (renal or hepatic dysfunction, cardiorespiratory disease, or binge alcohol use) to the use of metformin that could predispose her to its most significant side effect, lactic acidosis (see Case 53-16, Question 2). Because L.H. exhibits the typical features of insulin resistance syndrome and has no contraindications for its use, she should be started on metformin. For the purposes of this case, the ADA guidelines will be followed. However, it is important to note that the AACE guidelines suggest a more aggressive A_{1c} goal (<6.5%), and because L.H.'s current A_{1c} is between 7.5 and 9.0%, her case would merit dual therapy to delay progression disease (AACE). One trial found that dual therapy with metformin and DPP-IV inhibitor extended the time to treatment failure and therapy intensification.[307] Her A_{1c} goal, per the ADA guidelines, of <7% will require an additional 1.3% lowering in her A_{1c}, which can likely be achieved with metformin. However, any changes in her lifestyle will

further help lower her A_{1c}. L.H. should be instructed to initiate metformin at a dose of 500 mg twice daily with food.

Titrating metformin doses

Case 53-11, Question 4: L.H. is started on metformin 500 mg bid with food and instructed to increase her dosage to 500 mg every morning and 1000 mg every evening after 1 week. Three days after starting metformin, she phones the clinic reporting nausea and diarrhea. She admits to taking her doses on an empty stomach. How should L.H.'s symptoms be addressed?

GI disturbances such as diarrhea, bloating, anorexia, abdominal discomfort, nausea, and metallic taste often dissipate with time, and can be minimized by initiating metformin in a single 500- or 850-mg dose at breakfast or with the patient's largest meal of the day. Consistently taking metformin with food significantly minimizes the GI side effects. The dosage should be slowly increased (eg, 500 mg/day every 2 weeks) until the appropriate clinical effect is achieved or the patient is taking the maximal dose (1000 mg bid or 850 mg tid). Therefore, L.H.'s metformin dose should be reduced to 500 mg daily with her largest meal, and she should be titrated more slowly during a period of several weeks. Metformin is typically dosed two to three times daily (the long-acting formulation is dosed once daily with dinner). Twice-daily dosing for adherence purposes is preferred if a patient can tolerate a 1000-mg dose or once daily with the ER formulation. If she continues to experience GI symptoms, an alternative approach is to switch her to the ER formulation; small studies have demonstrated improved tolerability with the ER tablets versus the immediate-release dosage form.[308] A drawback to these tablets is their large size. Also, patients may report that metformin has a fishy odor,[309] which seems to be more apparent with certain generic formulations. If this is significant enough to cause a patient to stop taking it, the ER formulation can be tried, which may be more tolerable. One generic company offers blackberry-scented

metformin, which may also be a beneficial option if odor is an issue for patients.[310]

Monitoring metformin therapy

Case 53-11, Question 5: How should metformin therapy be monitored in L.H.?

As is standard with other agents, L.H. should be encouraged to perform SMBG (see Case 53-11, Question 6) and have an A_{1c} test drawn quarterly until she achieves consistent values <7%. Additional evidence of the therapeutic benefits of metformin may include an improved lipid profile and some weight loss. Initially, it is important to monitor GI problems, and although lactic acidosis is unlikely, L.H. should be warned to bring to the attention of her physician any sudden symptoms of shortness of breath, weakness, and malaise. A baseline SCr, eGFR, LFTs, and complete blood count should be obtained for L.H. and repeated yearly. Metformin can reduce vitamin B_{12} absorption, and it is associated with reductions in vitamin B_{12} levels (19% after 4 years of use in one study) and actual deficiency.[311,312] Therefore, monitoring of vitamin B_{12} levels every 2 to 3 years should be considered with long-term use.

SELF-MONITORING OF BLOOD GLUCOSE IN TYPE 2 DIABETES

Case 53-11, Question 6: L.H. is interested in learning how to perform BG testing. What are the advantages and disadvantages of SMBG tests? When and how often should L.H. be instructed to test her BG concentrations?

SMBG is an important self-management tool for patients such as L.H. to assess the efficacy of therapy and guide adjustments in nutrition, exercise, and medications. Disadvantages include cost of testing, inadequate understanding by both health care providers and patients regarding the benefits and proper use of SMBG results,

patient psychological and minor physical discomfort associated with obtaining a blood sample, and the inconvenience of testing. However, with the current advances in meter technology and proper patient education, most of these potential barriers can be overcome.

The ADA states that SMBG may be a useful guide for patients with type 2 diabetes treated with MNT or noninsulin therapies, although there is insufficient evidence to determine optimal frequency of testing and demonstrate cost-effectiveness for these patients. Although one meta-analysis of SMBG effects in patients with type 2 diabetes not on insulin concluded the overall effect on A_{1c} was a 0.4% reduction, others failed to show a benefit.[312] SMBG studies in patients with type 2 diabetes are often limited in that multiple interventions, such as education, diet, and medication adjustments, were used. However, a primary reason studies fail to show a benefit is that patients are not taught what to do with their BG numbers (ie, how to respond to a low BG reading); the BG values are solely used by the providers to make adjustments to their therapy.[313]

SMBG should be considered for most patients with type 2 diabetes, particularly those who are learning to adjust their carbohydrate intake and portion sizes and want to measure how well medications and lifestyle changes are working to improve their glucose control. Although not always cost-effective, testing four times daily before meals and at bedtime for 1 week is useful, so that the patient can observe his/her glucose profiles and determine the effect various types of food and physical activity can have on BG levels. Later, once the desired A_{1c} has been achieved, BG can be tested less frequently. Testing times should vary throughout the day so that fasting, postprandial, and bedtime values can be assessed. As emphasized by the ADA, intensive patient education regarding testing technique and interpretation are vital to the cost-effective use of this monitoring tool. The patient must learn how to respond to his/her glucose profile and institute lifestyle changes that can have a favorable effect.

Clinical Use of Antidiabetic Agents

CASE 53-11, QUESTION 7: L.H. was quite motivated to improve her glucose control because her grandmother "lost a leg" to diabetes and her aunt is undergoing dialysis because "her kidneys have failed." She is taking metformin 1000 mg PO bid and tolerating it reasonably well (she occasionally gets some stomach discomfort, but states she is fine with it). She is proud that she remembers to take the metformin every day as instructed. She met with a dietitian who suggested an 1800-calorie diet and 45-minute walks three times weekly. After 3 months, L.H. lost 6 pounds (2.72 kg). L.H. stopped drinking regular sodas and juices, but eats bread or two large tortillas at each meal. She admits to eating only small amounts of "greens" and vegetables. She has not been able to implement her walks three times weekly; more often, she only walks once a week. Although her FPG fell to 130 mg/dL, a majority of her postprandial BG levels were >180 mg/dL. Her A_{1c} is 7.4%, and fasting triglyceride levels are now 260 mg/dL. How should her therapy be adjusted? What factors should be considered when deciding on the next steps for pharmacologic therapy?

L.H.'s A_{1c} has improved by 0.9%. However, she has not fully instituted lifestyle interventions. Although she has cut out juices and regular sodas, she can still further improve her diet and lower her postprandial BG (to <180 mg/dL) by reducing her carbohydrate intake, switching to whole-grain breads, and increasing her vegetable intake. She also can increase her physical activity to at least three times weekly. Although the A_{1c} is not <7%, a reasonable approach would be to continue metformin at 1000 mg PO bid and reinforce lifestyle changes at this point before modifying her pharmacologic therapy.

The amount of A_{1c} lowering in response to adding an antidiabetic agent appears to depend on the baseline glycemic level. A meta-regression analysis of 61 clinical trials evaluated the efficacy of five classes of oral agents (sulfonylureas, glinides, metformin, TZDs, and α-glucosidase inhibitors).[314] Significant correlations were found between the baseline A_{1c} and FPG, and their mean decreases as a result of these agents. Greater reductions in A_{1c} and FPG were observed in groups with higher baseline levels. In addition, a meta-analysis of oral agents found that every 1% higher baseline A_{1c} level predicted a 0.5% greater reduction in the A_{1c} after 6 months of

therapy.[314] Overall, on initiation of noninsulin monotherapy, the A_{1c} will typically lower by ~1% to 1.25%.[315] One meta-analysis revealed that, on average, A_{1c} was lowered an additional (approximately) 1.2% in patients on long-acting GLP-1 agonists, 1.0% in patients on short-acting GLP-1 agonists, and 0.8% in patients on DPP-IV inhibitors[316] when combined with metformin. Another meta-analysis indicated that after 52 weeks in combination with metformin, SGLT-2 inhibitors may help lower A_{1c} an additional 0.11%.

If L.H. is not able to reach an A_{1c} of <7% with lifestyle interventions, the next step for her would be to add a second antidiabetic agent. Selecting an antidiabetic agent to treat type 2 diabetes has become more complex because new agents with unique mechanisms of action have been introduced into the market. Several considerations should be taken into account when choosing initial oral therapy for patients with type 2 diabetes. As with all therapeutic decisions, clinicians should also blend their knowledge of the drug (eg, its efficacy, safety, hypoglycemic risk, weight gain, other side effects, route of administration, and cost/hospital formulary) with the unique characteristics of the patient (eg, level of glycemic control, organ function, other concurrent diseases and medications, ability to adhere to complex medication regimens, and health insurance coverage) when making a choice of drug products.[42] The current A_{1c} level and reduction required to reach the A_{1c} goal is a key consideration.

Table 53-25 compares and contrasts the efficacy, advantages, and disadvantages of antidiabetic agents used to treat patients with type 2 diabetes, and can be used to help select drugs for a specific patient. The ADA guidelines provide recommendations on subsequent medications (after metformin) to select based on patient comorbidities, socioeconomic barriers, and other complications.

The AACE guidelines recommend consideration of initiating insulin therapy (most often basal insulin) if the A_{1c} is >9% with symptoms of hyperglycemia.[26] The ADA guidelines recommend choosing based on patient's level of hyperglycemia and if they are symptomatic.[62,64] It

is an option for dual therapy in all patients, especially if A_{1c} >9%, but should be strongly considered with an A_{1c} >10%.[63,306] Practitioners should attempt to avoid unnecessarily complex therapy that may confuse the patient, increase drug costs, and complicate the clinician's ability to assess each medication's contribution to the overall therapeutic outcome.

The ADA recommends initial therapy with lifestyle changes and metformin monotherapy. Early combination therapy can be used in some patients at treatment initiation to extend the time to treatment failure.[26] If the patient cannot tolerate metformin, other agents recommended for diabetes management may be used. These agents include sulfonylureas, TZDs, DPP-4 inhibitors, SGLT2 inhibitors, GLP-1 receptor agonists, and insulin. Selection of appropriate agents is discussed later in this chapter. If after 3 months of monotherapy the patient has not achieved their glycemic targets, a second agent may be added. If the patient still has not achieved their glycemic targets after 3 months of dual therapy, a third agent may be added. If glycemic targets still have not been reached after 3 months of triple therapy, different drug classes should be tried and a basal-bolus insulin approach may be considered.[26]

SELECTING AN ALTERNATIVE TO METFORMIN AS MONOTHERAPY

CASE 53-11, QUESTION 8: Which other antidiabetic agents could be considered for L.H. as monotherapy if she cannot tolerate metformin therapy?

Although the ADA recommends the use of metformin, in combination with lifestyle modification, as first-line therapy, other antidiabetic agents are approved for use as monotherapy as well. L.H. is a typical overweight patient with type 2 diabetes with early evidence of CVD (hypertension), but with no evidence of microvascular complications. Her liver, renal, and GI functions are normal. Patients such as L.H. have varying degrees of β-cell dysfunction and tissue resistance to insulin. In these individuals,

pulsatile insulin secretion and first-phase insulin release are absent, and the pancreas is “blind” or unresponsive to high glucose concentrations (glucotoxicity). Because target tissues are less responsive to insulin, hepatic glucose output typically is increased, and higher concentrations of insulin may be needed for peripheral glucose utilization. Insulin causes more weight gain and hypoglycemia than do the other antidiabetic agents, and is usually reserved for combination therapy unless the initial A_{1c} at diagnosis is very elevated (>10%) or ketonuria is present.[317]

Often, acarbose is eliminated from consideration because slow titration is required to minimize GI effects; anecdotally, however, people of Mexican American origin, such as L.H., seem less susceptible to flatulence and diarrhea. Also, because acarbose has less dramatic effects on the FPG (20–30 mg/dL decrease) and A_{1c} (0.5%–1.0% decrease) than have the other agents, biochemical goals are less likely to be achieved in patients whose A_{1c} is 8.5% or higher.

Pioglitazone also can be used as monotherapy, and, similar to metformin, will not cause hypoglycemia, but weight gain and edema are likely. On the positive side, the TZDs have been shown to have better “glycemic durability” compared with metformin and the sulfonylureas. In a double-blind, randomized, controlled trial of 4360 patients with type 2 diabetes, time to monotherapy failure, defined as FPG >180 mg/dL, was assessed for rosiglitazone, metformin, and glyburide (A Diabetes Outcome Progression Trial [ADOPT]).[318] Patients were treated for a median of 4 years. The Kaplan–Meier analysis showed that the cumulative incidence of failure at 5 years was 15% for rosiglitazone, 21% for metformin, and 34% for glyburide ($P < .0001$). The suggested explanation for the favorable rosiglitazone results was that it slowed the rate of β-cell function decline. On the negative side, TZDs are associated with many adverse effects, including an increased risk in bone fractures and HF.[213,215] TZDs are associated with an approximately twofold increased risk of HF and thus are contraindicated in NYHA classes III to IV HF.[317] In the long-term ADOPT trial, rosiglitazone was

associated with a mean weight gain of 10.58 pounds (4.8 kg), whereas weight decreased by 6.39 pounds (2.9 kg) in the metformin group; glyburide-treated patients had a mean weight gain of 3.53 pounds (1.6 kg) during the first year, and then remained stable.[26,42] The TZDs also have been found to reduce bone density and increase fracture risk. Given the adverse effects associated with TZDs, and the availability of other agents, their use has fallen out of favor.

Sitagliptin, saxagliptin, and exenatide, which are approved for monotherapy, are often reserved for combination therapy. However, DPP-4 inhibitors may be useful as monotherapy for patients in whom the use of other oral agents is precluded (such as renal dysfunction with metformin or severe HF with pioglitazone). Of note, saxagliptin and alogliptin are not recommended in patients with HF. GLP-1RAs may be particularly useful in obese patients.[42] It should be noted that AACE recommends GLP-1RAs as first line if metformin cannot be used initially.[319,320]

For several years, sulfonylureas were used successfully to treat patients with type 2 diabetes. Although these agents lower A_{1c} significantly as monotherapy (~1%–1.5%), there are still several issues with this class of medications such as hypoglycemia, weight gain, diminished durability, and poor lipid profile. Although the use of these agents has fallen out of favor because of these effects, they are still often utilized when cost is a concern for a patient (Table 53-26).

Several products that combine two oral agents into one medication are available. Although many of these products are approved as first-line therapy, consider reserving them for use in patients who are already established on two agents or whose medication regimens must be simplified to enhance adherence or decrease cost. Based on this discussion, metformin is favored as initial therapy in L.H.

CASE 53-12

Question 1: N.H. is a 46-year-old, obese (BMI 33 kg/m^2) male with a history of type 2 diabetes, and hyperlipidemia. He presents with fatigue and nocturia. N.H.

used to smoke two packs of cigarettes per day for 15 years, but he quit after his diabetes diagnosis. He has a strong family history of CHD. At diagnosis 3 months ago, an elevated A_{1c} was documented (7.6%), confirming the diagnosis of type 2 diabetes. Test reports of liver and renal functions are within normal limits. Current medications include lisinopril and atorvastatin. N.H. started metformin, but stopped taking it because of GI symptoms (loose stools); he refuses to try this medication again.

What is a reasonable next monotherapy option for N.H.?

Unfortunately, N.H. did not tolerate metformin. Although this is less common if patients take metformin with food, the dose is titrated slowly or are switched to the ER formulation, some do not overcome the GI adverse effects. N.H. is refusing to even consider a retrial. An A_{1c} goal of <7% may be appropriate for N.H., although given his young age and long life expectancy, a target of <6.5% would be appropriate. Therefore, the A_{1c} lowering required to get to the goal is only 0.6% to 1.1%.

With a BMI of 33 kg/m^2, hypertension, and dyslipidemia, N.H. has many components of the metabolic syndrome and insulin resistance (see section on Pathogenesis). Sulfonylureas or insulin would not be an optimal next choice of drug for N.H. because they do not exert a favorable effect on plasma lipids and are generally associated with weight gain and hypoglycemia. Although the A_{1c} is elevated, it still does not merit insulin therapy. However, it must be acknowledged that some sulfonylureas remain the least expensive oral antidiabetic agents, and this may be an important factor in the initial selection of therapy for some patients. Acarbose as monotherapy is not likely to attain near-normal plasma glucose concentrations. Pioglitazone improves peripheral target tissue responses to insulin and lipid profiles; however, because N.H. is obese, it would be prudent to avoid pioglitazone because of weight gain (see Case 53-11, Question 8, and Case 53-15). A GLP-1 agonist, DPP-4 inhibitor, or an SGLT-2 inhibitor are reasonable options for N.H. because they are not associated with weight gain (GLP-1 agonists and SGLT-2 inhibitors may even promote weight loss).

DPP-IV inhibitors may be used in the case of N.H. if he is reluctant to inject; however, these agents usually are weight neutral and modestly decrease A_{1c}. Sitagliptin 100 mg may be started once daily to help achieve glycemic goals and to avoid hypoglycemia. Another oral option may include an SGLT-2 inhibitor, such as empagliflozin 25 mg daily, which has weight loss benefit, renal and CV protection, and a low risk of hypoglycemia.

For N.H., initiation of a GLP-1RA, such as liraglutide, may be the most beneficial option for weight loss. A GLP-1RA, along with lifestyle changes, can help N.H. achieve the A_{1c} goal and would be a good option for N.H. if he is willing to use an injectable medication. If liraglutide is used, it should be initiated at a dose of 0.6 mg once daily for 1 week and then increased to the therapeutic dose of 1.2 mg once daily thereafter. Some patients may require further titration to 1.8 mg once daily to reach their glycemic goals. N.H. should be counseled about the likelihood of GI side effects, which should subside over time, as well as the rare risk of pancreatitis (and to stop taking and notify his provider if he has persistent severe abdominal pain that may radiate to the back and vomiting) and severe allergic reactions. Once-weekly GLP-1RAs, such as semaglutide, dulaglutide, and exenatide ER, would also be appropriate options and potentially improve adherence (see section on GLP-1RAs for specific dosing recommendations). Before choosing a specific GLP to be initiated in any patient, one must consider patient preference in terms of cost and dosing.

N.H. was successful in reducing his A_{1c} to 6.4% through a combination of lifestyle modifications and liraglutide. He was able to lose 10 pounds (4.54 kg) with walking and reduction in fatty food.

N.H. quit smoking 3 months ago. Smoking has been shown to increase the risk of IFG and type 2 diabetes.[321] The mechanism for this is thought to be related to increased insulin resistance and oxidative stress and reduced insulin secretion. Smoking also increases the risk of microvascular and macrovascular disease in people with diabetes.[322] Therefore, N.H. should be congratulated on his cessation, and continued abstinence should be encouraged

through follow-up visits (see Chapter 91, Tobacco Use and Dependence). If needed, pharmacologic intervention for the treatment of smoking cessation could be recommended.

Failure of Antidiabetic Monotherapy

PATHOGENESIS

CASE 53-13

QUESTION 1: Q.R. is a 68-year-old, 61 inches (154.94 cm), 165-pound (74.84 kg; BMI, 31.2 kg/m^2) female with an 8-year history of type 2 diabetes who has been treated with diet, exercise, and metformin. According to clinic records, she was well controlled initially (A_{1c} 6.7%–7.2%) for the first 5 years. When her glycemic control worsened (FPG, 130–160 mg/dL; A_{1c}, 7.5%–8.5%), her metformin dose was increased from an initial dose of 500 mg bid to her current dose of 1000 mg bid. Recent chart notes indicate that Q.R.'s chief complaints have included loss of appetite and fatigue. Her current A_{1c} is 8.4%. Other medical problems include hypertension managed with hydrochlorothiazide 25 mg daily and mild peripheral neuropathy managed with acetaminophen 500 mg bid. Her eGFR is 70 mL/minute.

At this clinic visit, Q.R., who is well known to you, seems particularly listless and flat in her affect. Her BG records, which are typically meticulous, are incomplete. Morning fasting BG values consistently exceed 200 mg/dL and range from 202 to 340 mg/dL. While taking her history, you discover that her husband passed away last year and that one of her adult children has recently been diagnosed with a terminal illness.

What factors may be contributing to Q.R.'s poor glucose control?

Several factors may be contributing to Q.R.'s deteriorating BG control and apparent lack of responsiveness to maximal dose of metformin during the past year (as evidenced by her elevated BG and A_{1c}, listlessness, and lack of appetite). Monotherapy failure (also called secondary failure) is characterized by progressively poor glucose control that occurs after a period of good response (months to years). The cause of failure may be related to progressive pancreatic failure; poor adherence to diet, exercise, or medications; and exogenous diabetogenic factors such as increased weight,

illness, or drugs that induce hyperglycemia (eg, atypical antipsychotics or glucocorticoids).

Type 2 diabetes is a progressive condition, which is most likely to require combination drug therapy. The UKPDS confirmed that monotherapy failure represents a natural progression of type 2 diabetes. In this study, only 16% and 19% of the subjects achieved an FPG <108 mg/dL and A_{1c} <7%, respectively, after 3 years of dietary therapy alone.[322] By 9 years, only 9% were able to maintain their glycemic goals using just diet therapy. The investigators also found monotherapy failure occurred at the same rate regardless of the initial treatment selected: glyburide, chlorpropamide, metformin, or insulin. In all the monotherapy treatment groups, patients required additional therapies over the course of the study duration.[317] At 3 years, fewer than 55% of patients randomly assigned to single-pharmacologic therapy could maintain an A_{1c} <7%, and by 9 years this dropped to about 25% of patients. In the ADOPT study, patients were able to maintain A_{1c} levels <7% using monotherapy for 60, 45, and 33 months with rosiglitazone, metformin, and glyburide, respectively.[323] The reason for glycemic deterioration is likely owing to the natural progression of type 2 diabetes in which β-cell function declines with increased duration of disease.

Q.R.'s deteriorating control on a therapeutic dose of metformin after 5 years of reasonable response is consistent with the natural progression of type 2 diabetes. However, the stress and depression arising from her life situation have no doubt contributed to her poor control. The latter may have led to a change in her usual adherence to diet, exercise, and medications, and should resolve with time and appropriate management. Females with type 2 diabetes are at increased risk for depression. Evidence exists for a bidirectional association between diabetes and depression in females.[324] Although hyperglycemia has been attributed to hydrochlorothiazide, the dose prescribed for Q.R. has few adverse metabolic effects.

MANAGING MONOTHERAPY FAILURE

Case 53-13, Question 2: How should Q.R. be managed? What is an appropriate antidiabetic agent to add?

Q.R. is exhibiting symptoms of depression (eg, listlessness and flat affect). Her depression likely started after her husband's death. Every effort must be made to address Q.R.'s depression because it is unlikely that she will be able to effectively implement more aggressive treatment of her diabetes until her situation is improved. Resources that may be used include her family, a therapist, and a social worker.

Treatment of monotherapy failure includes identifying and correcting any diabetogenic factors and altering her drug therapy. When failure to any oral agent occurs, one should always add another agent rather than switch to another, unless adverse effects are intolerable, or contraindications warrant the discontinuation of the drug. This is supported by a study that evaluated the effect of metformin alone in a population of patients who had failed oral sulfonylureas and the effect of metformin plus the sulfonylureas. Substitution of metformin for glyburide did not produce any significant change in glycemic control, but the addition of metformin to glyburide therapy substantially improved glucose concentrations.[325] Many combinations of antidiabetic agents can be used. The key is that they should have different mechanisms of action. For example, it is not reasonable to combine a sulfonylurea with a glinide (ie, repaglinide and nateglinide) because they are both insulin secretagogues. Options for Q.R. include adding one of the following to metformin (in no particular order): insulin secretagogue (sulfonylurea or glinide), acarbose, TZD (pioglitazone), DPP-4 inhibitor (sitagliptin, linagliptin, alogliptin, or saxagliptin), SGLT-2 inhibitors (canagliflozin, dapagliflozin, empagliflozin, or ertugliflozin), or a GLP-1 agonist (exenatide, exenatide ER, liraglutide, lixisenatide, dulaglutide, or semaglutide or semaglutide oral).

Table 53-25 summarizes the FDA-approved combination therapy indications. Insulin therapy may be considered at this time; however, because Q.R.'s A_{1c} can be lowered to <7% with an additional

noninsulin agent, two noninsulin antidiabetic agents should be utilized first. In addition, the ADA recommends that if an injectable agent is necessary for treatment, a GLP-1 agonist should be initiated first, before insulin. In summary, patients such as Q.R. who are unresponsive to the maximally effective dose of metformin should be initiated on combination, noninsulin therapy.

When agents from different antidiabetic classes are combined, their effects are additive. With the availability of many antidiabetic agents, there is no one best combination therapy for A_{1c} lowering. As discussed, the choice of therapy should take into account the patient's organ function, the amount of A_{1c} lowering required to reach an individual's goal, comorbidities (ie, HF, CKD, ASCVD), possible adverse effects of a particular drug or drug combination, cost, hypoglycemia risk, and patient preference.

A mixed-treatment comparison meta-analysis evaluated the efficacy of second-line antidiabetic therapy added to patients on stable doses of metformin.[256] The risk of weight gain and hypoglycemia was also determined. A total of 27 randomized controlled trials were included in the analysis, with a mean study duration of 32 weeks. The different agents had similar A1C reductions. TZDs, sulfonylurias, and glinides had more weight gain, and sulfonylureas had more hypoglycemia. In addition, the change in A_{1c} depending on the baseline level of A_{1c} was evaluated and found, as previously discussed (see Case 53-11, Question 7), to be greater when the baseline A_{1c} was ≥8%.

Q.R. is not opposed to injections, but would rather take oral medications to manage her diabetes. Because she is postmenopausal, avoid a TZD owing to the concerns of increased risk of fractures. Sulfonylureas are a cheaper option; however, it may contribute to weight gain. Given the significant GI side effects associated with the α-glucosidase inhibitors, their use is often avoided all together. The DPP-4 inhibitors may be an option; however, they may have only moderate A_{1c} lowering capacity. SGLT-2 inhibitors are an excellent option for this patient because they can help further reduce A_{1c} and help with Q.R.'s comorbidities (obesity).

Combination Antidiabetic Therapy

Case 53-13, Question 3: Q.R. is started on empagliflozin 25 mg/day and continued on metformin 1000 mg bid. This improved her FPG and A_{1c} modestly for ~12 months (FPG, 120–150 mg/dL; currently A_{1c}, 7.6%). She has heard about a new, injectable class of diabetes medications that cause weight loss. Is she a candidate for this new class of medication?

It quickly becomes apparent that Q.R. is referring to the GLP-1 agonists, (exenatide, exenatide ER, liraglutide, lixisenatide, dulaglutide, semaglutide, and semaglutide oral); only semaglutide is on her health plan's formulary. Q.R. states that she has no history of thyroid cancer or pancreatitis.

When the A_{1c} is above goal despite the use of a combination of two agents, practitioners often add a third agent before considering insulin. Although this is tempting, depending on a patient's current level of glycemic control, this practice only delays insulin therapy, which is likely to be required to achieve A_{1c} goals. However, because Q.R. is close to an A_{1c} level of <7%, it is reasonable to try a third, noninsulin antidiabetic agent.

Semaglutide has been studied as monotherapy and also in combination with metformin and basal insulin. These studies have indicated that semaglutide 0.5 or 1.0 mg once weekly in combination with metformin may help lower A_{1c} by 1.0% to 1.5% (Ozempic® powder inhaler [PI]). Thus, for Q.R., the addition of semaglutide could result in an A_{1c} of <7%. If Q.R. were on a sulfonylurea, there may be a heightened risk of hypoglycemia when used in combination with semaglutide. Therefore, if this combination is used, the dose of the sulfonylurea on initiation of semaglutide may need to be lowered to minimize the risk of hypoglycemia. Adjustments can be made based on the patient's glycemic response to liraglutide accordingly.

Q.R. should be started on semaglutide 0.25 mg SC once weekly for 4 weeks, independent of meals. After 4 weeks, Q.R. should increase the dose to 0.5 mg SC once weekly if tolerated. She can further increase the dose to 1.0 mg if further glycemic control is

needed. Q.R. should be counseled about nausea and diarrhea, which are the most frequent side effects. Her A_{1c} should be reevaluated after 3 months of being on at least the 0.5 mg dose. An advantage of semaglutide is the potential for weight loss and CV benefit. One multicentered, randomized controlled trial, compared semaglutide to placebo and showed a significant 26% reduction in time to first occurrence of death from CV causes, nonfatal MI, nonfatal stroke. In addition, mean body weight was found to be significantly decreased by 6.39 pounds (2.9 kg) and 10.80 pounds (4.9 kg) for the 0.5 and 1.0 mg semaglutide groups, respectively.[256]

Q.R. should be counseled about the rare risk of pancreatitis. Also, if she finds that nausea is significant enough to reduce her fluid intake, she should contact her provider. There have been postmarketing reports of altered renal function and renal failure with semaglutide, which are likely owing to dehydration from reduced fluid intake because of GI side effects (ie, nausea, vomiting, and diarrhea). Semaglutide was also found to increase the absolute risk of worsening diabetic retinopathy. Q.R. should have an annual ophthalmic examination.

A small proportion of patients will form anti-semaglutide antibodies. Antibody formation did not equate with reduced efficacy of liraglutide when examining mean A_{1c} levels between antibody-positive and antibody-negative patients. It is important to note that any of the available GLP-1RAs are options for Q.R. for initial GLP-1RA therapy. Discussions should be regarding adherence, efficacy, side effects, and cost.

Combination Antidiabetic With Insulin Therapy

Case 53-13, Question 4: If Q.R.'s therapy failed and she required insulin based on continuously elevated A_{1c} levels, why would it be reasonable to use insulin in combination with other antidiabetic agents? How should it be combined with other agents? Is this combination more effective than is insulin alone?

Most patients with type 2 diabetes eventually require insulin. The combined use of insulin with a variety of oral agents has been extensively evaluated, but the studies differ in their interventions. In some studies, single doses of an intermediate- or a long-acting insulin or once- or twice-daily doses of premixed insulin are added to a single or combination of oral antidiabetic agents in poorly controlled patients. The primary outcomes that have been evaluated include measures of glycemic control (eg, A_{1c}, FPG) and the extent to which insulin doses have been decreased. DeWitt and Hirsch published a comprehensive review of these studies, and readers are referred to this article for this evidence.[104] The combined use of insulin and oral agents can be considered based on the AACE algorithm, particularly when the A_{1c} is higher than ~9%.

Before starting insulin, it is important to review the BG profile:

- Fasting hyperglycemia, which may improve or persist throughout the day: This is the more typical glucose profile for patients with type 2 diabetes, in whom addition of basal insulin at nighttime would be the most appropriate next step.
- Fasting BG is at target, with daytime hyperglycemia: This is less common for people with type 2 diabetes, in whom addition of prandial insulin would be an appropriate next step for therapy (see Case 53-13, Question 5).

In Q.R.'s case, it makes the most sense to add a single dose of basal insulin to metformin, empagliflozin, and semaglutide. Advantages attributed to adding insulin to an oral agent as the next step after failure, as opposed to using insulin alone, include the following[104]:

- Lower insulin dosages can be used, and this minimizes weight gain and hypoglycemia.
- Simpler, single-dose insulin regimens are possible (vs monotherapy with insulin).
- Lowering the fasting glucose concentrations improves glucose control throughout the day because glucose excursions related to

meals are layered over lower values. Furthermore, lower glucose values improve β-cell responsiveness to glucose and enhance tissue responsiveness to insulin action.

However, lowering glucose concentrations is the first priority, not attempting to use lower insulin doses. Q.R. should be started on 10 units or 0.1 to 0.2 units/kg of NPH, or basal insulin glargine, detemir or degludec. This dose is based on empiric use of insulin in a variety of studies (0.1–0.2 units/kg)[326] and a conservative estimate for basal insulin of ~0.5 units/hour (Q.R. weighs 155 pounds [70.31 kg]). The dose also takes into account the possibility that Q.R. is secreting some basal insulin of her own. The basal dose should be titrated upward based on the FPG for 3 consecutive days. A common titration method used is the "treat-to-target" schedule.[103,327]

FPG (mg/dL)	Adjustment of Basal Insulin Dose (Units)
≥180	8
160–180	6
140–159	4
120–139	2
100–119	1
80–99	Maintain dose.
60–79	−2
<60	−4 or more

Alternatively, the basal insulin dose can be increased by 2 units every 3 days until the FPG is in a target range (80–130 mg/dL); if the FPG is >140 to 180 mg/dL, larger increments can be used (eg, by 4 units every 3 days).[326] If hypoglycemia occurs or the FPG is <80 mg/dL, the dose should be reduced by at least 4 units, or by 10% if the dose is >60 units. Of note, if U-300 glargine and U-100 and U-200 degludec are used, doses should not be titrated sooner than every 3 to 5 days. If there is no improvement in glycemic control after 3 months, prandial insulin or a GLP-1RA (if not already being used) should be added to the patient's regimen (see Case 53-13,

Questions 5 and 6). In the setting of insulin resistance, such as with type 2 diabetes, continuing metformin therapy should be a priority if possible.

Overbasalization may occur with basal insulin therapy. Clinical signals that may prompt evaluation of overbasalization include basal dose >~0.5 units/kg, high bedtime–morning or postprandial–preprandial glucose differential (eg, bedtime–morning glucose differential ≥50 mg/dL), hypoglycemia (aware or unaware), and high variability in BG measurements.[62,328]

Insulin Monotherapy in Patients With Type 2 Diabetes

INSULIN REGIMENS

Case 53-13, Question 5: Q.R. was initiated on insulin glargine and titrated to 25 units at bedtime. In combination with empagliflozin 25 mg/day, semaglutide 1.0 mg once weekly, and metformin 1000 mg bid, her fasting glucose levels fell to the 110s and 120s on most occasions; her A_{1c} dropped to as low as 6.9%. However, after 1 year, she began to note a gradual rise in glucose concentrations throughout the day. This resulted in a further increase in her bedtime insulin glargine to 40 units (0.57 units/kg). Currently, her morning BG levels are 120 to 140 mg/dL, and BG levels before or after meals range between 170 and 200 mg/dL. A recent A_{1c} value was 8.5%. For the past 6 months, Q.R. has noted increasing fatigue, bouts of blurred vision, and polyuria. How should she be managed now?

The next step in managing Q.R.'s diabetes is to institute prandial insulin therapy, which is needed as indicated by her daytime hyperglycemia. Like patients with type 1 diabetes, those with long-standing type 2 disease may require prandial insulin before meals to minimize postprandial excursions. Insulin lispro has been shown to decrease postprandial glucose concentrations to a greater extent than has regular insulin (30% lower at 1 hour and 53% lower at 2 hours) and was associated with a lower rate of hypoglycemia, particularly between midnight and 6:00 AM (36%). However, A_{1c}

levels were not significantly different after 6 months.[329] A similar response with insulin aspart, glulisine, and lispro-aabc would be expected.

Because Q.R. is on insulin glargine, the most appropriate next step is to add prandial insulin using a rapid-acting insulin. Initiation of basal-bolus insulin regimens are discussed in detail in the section on Type 1 Diabetes Insulin Therapy (see Case 53-2, Questions 4–6). An easy way to introduce prandial insulin is to initially add only one mealtime dose. The premeal BG levels that are associated with the most hyperglycemia are targeted. For example, if the prelunch BG levels are elevated, a prandial dose at breakfast is added; or if the bedtime BG levels are mainly elevated (owing to large dinners), a prandial dose at dinner is added. Once a patient adjusts to this, prandial insulin is added to the other meals. Patients with type 2 diabetes may require large insulin TDDs (>1 unit/kg) to reach A_{1c} targets <7%. Although not technically insulin monotherapy, metformin, empagliflozin, and semaglutide can be continued to assist in reducing insulin resistance and minimizing weight gain with insulin.

PREMIXED INSULINS

CASE 53-13, QUESTION 6: Q.R. has difficulty adhering to a basal-bolus insulin regimen. She is currently taking insulin glargine 38 units at nighttime and ~7 units of insulin aspart before each meal (she follows a high-sugar correction scale). What options are available for Q.R.?

Because people with type 2 diabetes retain some pancreatic function, it often is possible to achieve an acceptable level of control with twice-daily doses of intermediate-acting insulin in combination with rapid- or short-acting insulins, which are available as premixed insulins. These are referred to as *split-mixed insulin regimens*. Although convenient, they do limit flexibility in dosing, and thus A_{1c} lowering ability without increasing hypoglycemia risk. In the United States, fixed mixtures of NPH and regular insulin in a 70:30 ratio and

a 50:50 ratio are available (see Table 53-6). Commercial combinations of the rapid-acting insulins plus an intermediate-acting insulin also are available as Humalog® Mix 75/25™ (a mixture of insulin lispro plus lispro protamine suspension), Humalog® Mix 50/50™ (a mixture of insulin lispro plus lispro protamine suspension), and NovoLog® Mix 70/30™ (a mixture of insulin aspart plus aspart protamine suspension). These fixed mixtures are also available in prefilled syringes, which can add to their flexibility and convenience for administration.

The Treating to Target in Type 2 Diabetes (4-T) study assessed the efficacy of a basal insulin (detemir), prandial insulin (insulin aspart), and biphasic insulin (NovoLog® Mix 70/30™) regimen added to patients on metformin and a sulfonylurea.[330] After 3 years, a biphasic-based insulin regimen was found to be less effective in achieving an A_{1C} goal of <6.5% compared with prandial and basal insulin regimens (31.9%, 44.7%, and 43.2%, respectively). Despite the findings of this large multicenter study, use of twice-daily, premixed insulin remains a common insulin therapy for patients with type 2 diabetes.

Q.R. is currently receiving a TDD of insulin of 59 units, or 0.84 units/kg/day. To convert her to a premixed insulin, one could begin with a conservative TDD of 0.5 to 0.6 units/kg/day, split equally before breakfast and dinner. An older method of two-thirds in the morning and one-third in the evening is used less commonly now. When starting an insulin-naive patient with type 2 diabetes on premixed insulin, doses of 5 to 6 units twice daily (administered before breakfast and dinner) are often used, with the doses being titrated before breakfast (to affect prelunch and predinner glucose levels) and before dinner (to affect the bedtime and fasting glucose levels).[103,331]

If the premixed insulin does not achieve adequate glycemic control, an option is to mix the short- or rapid-acting insulin with NPH in the same syringe. By doing this, each insulin dose can be individually adjusted. A disadvantage to this is the chance for patients to make errors in measuring and mixing insulin, especially in

the elderly when they may have vision and/or dexterity issues. Alternatively, a prandial dose of rapid-acting insulin (ie, a third injection) can be added at lunch; the breakfast dose of premixed insulin should be decreased as well.[104] Another option is to add a third dose of the premixed insulin at lunch (so premix insulin tid); however, the lunchtime dose is smaller than are the breakfast and dinner doses. An initial premixed insulin lunchtime dose of 2 to 6 units, or 10% of the current TDD of premixed insulin, can be started.[332]

Q.R. should be started on a rapid-acting premixed insulin twice daily, because this has the convenience of being administered right before eating (within 15 minutes). A dose of 20 units SC bid represents a conservative starting dose. She should monitor her fasting and predinner BG levels, at a minimum, to further adjust her insulin doses.

Adding Antidiabetic Agents to a Basal Insulin Therapy–Based Regimen

CASE 53-14

Question 1: M.A., a 62-year-old female, has had type 2 diabetes for 11 years. She is currently taking metformin 1000 mg PO bid and insulin glargine 47 units at bedtime. Her A_{1c} is 8.2%. She tries to follow a meal plan that a dietitian developed for her, but her BMI remains 31 kg/m^2. Her physical activity is limited because of an arthritic knee, for which she plans to have knee replacement surgery in the future. Other medical problems include hypertension (hydrochlorothiazide 25 mg daily and benazepril 40 mg daily) and dyslipidemia (atorvastatin 40 mg daily), which are both well controlled.

Can any antidiabetic agents be added to her current therapy?

The TZDs have been well studied in patients with type 2 diabetes who are already taking insulin. In a meta-analysis, pioglitazone lowered A_{1c} by 0.58% when added to insulin therapy; unfortunately, it was associated with weight gain (6.61 pounds [3 kg]) and increased peripheral edema, and, therefore, should be avoided.[237]

A GLP-1 agonist would be a logical agent to consider adding for obese patients. Any GLP-1RA would be a good option. The agents should be chosen based on cost, effectiveness, and adherence. For example, exenatide may be the only GLP-1RA on formulary, or perhaps M.A. has trouble remembering to take once-weekly medications, such as dulaglutide, and as such would be more successful with once-daily liraglutide. Alternatively, an SGLT-2 inhibitor can be utilized because it also promotes weight loss. If additional glycemic control is needed after either is initiated, then the ADA guidelines support using the other agent.[62] Adding a DPP-4 inhibitor would be another option and would be weight neutral. Sitagliptin is FDA approved for use with insulin; however, the A_{1c} lowering may be less than that with a GLP-1 agonist.

Therefore, addition of liraglutide may be a reasonable approach in M.A. Her A_{1c} can reach her target goal of <7%, with potential for weight loss and lower insulin glargine requirements. Liraglutide should be initiated at a dose of 0.6 mg injected SC once daily for 1 week, after which the dose should be increased to 1.2 mg once daily. Some patients may require further titration to a maximum dose of 1.8 mg once daily to reach their glycemic targets. Another option would be to use a fixed ratio combination insulin/GLP-1RA such as liraglutide/degludec U-100, which provides a maximum daily degludec insulin dose of 50 units, and liraglutide 1.8 mg or lixisenatide/glargine U-100, which provides a maximum glargine insulin dose of 60 units and lixisenatide 20 µg.

Uses of Antidiabetic Agents in Special Situations

HYPOGLYCEMIA

CASE 53-15

QUESTION 1: C.A. is a 73-year-old female who has had a 20-year history of type 2 diabetes and a 5-year history of mild renal dysfunction (SCr, 1.2 mg/dL; eGFR, 47 mL/minute/1.73 m^2; BUN, 22 mg/dL). Her son, who lives with her, quickly called 9-1-1 when he noticed his mother appearing lethargic and sleepy,

with her eyes closed, as she was sitting on the couch. He assumed she was having a "low sugar reaction." When the paramedics arrived, her BG concentration was 46 mg/dL. C.A. was able to be aroused, and indicated she could drink something, so 4 ounces of orange juice was administered. After 10 minutes, her BG level was 80 mg/dL, so she was given another 4 ounces of juice. According to her son, C.A.'s diabetes has been well controlled for the past several months with glyburide 10 mg bid and metformin 850 mg tid. For the past 3 days, C.A. has been eating less and vomiting on association, with the "flu."

What was the likely cause of her hypoglycemic episode? Were there any predisposing factors?

C.A. is likely experiencing a hypoglycemic episode secondary to glyburide. Hypoglycemia is the most common and potentially severe adverse effect of the sulfonylureas, especially in the elderly population. The incidence and severity of this effect increase with the duration of action and potency of the agents.

Most sulfonylurea-induced hypoglycemia occurs in patients who are predisposed to hypoglycemia in some way, and C.A. is no exception. She is an elderly female with renal impairment who was on relatively high doses of an agent, a portion of which is excreted unchanged in the urine. Even in the face of decreased carbohydrate intake (reduced appetite and vomiting), she continued to take her usual dose of glyburide. Even though the stress of illness most often raises glucose levels, the decreased food intake resulted in glyburide causing hypoglycemia. Because glyburide has a long duration of action, hypoglycemia may last for several hours.

C.A. and her son should be educated about treatment of hypoglycemia. It is likely that her son did not need to call 9-1-1, and he could have treated the hypoglycemia. Glucagon (Glucagon emergency kit, GVOKE® or Baqsimi®) should not be used to treat hypoglycemia caused by a sulfonylurea, BECAUSE glucagon can cause a paradoxic fall in the glucose levels.[333]

RENAL DYSFUNCTION

CASE 53-15, QUESTION 2: C.A. has mild renal insufficiency (eGFR, 47 mL/minute/1.73 m^2 and is taking the maximal dose of metformin. How should

age and kidney function be taken into account with metformin use? Which agents should be avoided? Which agents could be used?

Sulfonylurea compounds that are metabolized to active products that depend on the kidney for elimination (eg, acetohexamide, chlorpropamide glyburide, and tolazamide) should be avoided in the elderly and in patients with decreased renal function. Sulfonylureas that are completely metabolized to inactive or weakly active products may be used (ie, glipizide, glimepiride, or tolbutamide). Although glyburide is unlikely to accumulate in patients with a CrCl >30 mL/minute, it should not be used in C.A. because it caused a severe hypoglycemic reaction.[334] C.A. should be instructed to eat regularly because skipped meals may result in recurrent hypoglycemia. Discontinuing the sulfonylurea and adding an agent with a lower incidence of hypoglycemia should be considered.

Although metformin rarely is associated with lactic acidosis, the manufacturer and the FDA have taken extreme measures to prevent its improper use because another biguanide, phenformin, which induced this life-threatening condition, was removed from the market in 1977.[335] The estimated rate of phenformin-induced lactic acidosis was 0.25 to 4 cases per 1000 users versus 5 to 9 cases per 100,000 users for metformin. A group of clinicians from the FDA summarized 47 confirmed cases of metformin-related lactic acidosis (lactate levels ≥5 mmol/L) that had been reported to the FDA between May 1995 and June 1996.[321] Unfortunately, the condition continues to be resistant to treatment; the mortality rate was 43%. Importantly, 43 of the 47 cases (91%) had concurrent conditions that predisposed them to lactic acidosis. These included cardiac disease (64%), decreased renal function (28%), and chronic pulmonary disease (6%). Several patients (17%) were older than age 80 years and may have had decreased renal function despite normal SCr concentrations. Interestingly, 38% of the patients had HF, and those who died were more likely to be under treatment with digoxin and furosemide. The mean daily dose of metformin was well within the therapeutic range and was not higher in the group that succumbed (1259 ± 648 mg in the group that died and 1349 ± 598 mg in the group that survived).

Metformin should be initiated with care in patients older than age 80 years because of the potential for a low GFR, even when SCr is normal.[190] Because C.A. has moderate renal dysfunction (GFR <60 mL/minute, but >40 mL/minute), her dose of metformin should be decreased to 500 mg bid to minimize the potential for accumulation.

The TZDs are primarily metabolized by the liver, and are not contraindicated in patients with mild renal failure. The use of pioglitazone, beginning with low doses, could be considered, as can acarbose, which is poorly absorbed from the GI tract. The DPP-4 inhibitors could also be used, but their doses may require adjustment depending on the degree of renal dysfunction (except for linagliptin).

SGLT-2 inhibitors can be beneficial in this patient population. C.A. has an eGFR of 47 mL/minute/1.73 m^2, and thus meets the renal cutoff for this class of medications. Empagliflozin, dapagliflozin, and canagliflozin all demonstrated reduction in CKD progression in CV outcome trials.[279,281,283] Dapagliflozin and canagliflozin were tested in separate trials, and were both found to significantly reduce the sustained decline of eGFR in patients with CKD.[282,284]

GLP-1 agonists are recommended in patients with CKD if SGLT-2 inhibitors are not tolerated. Exenatide can be used in patients with CrCl >30 mL/minute, and the dose does not need to be adjusted. Liraglutide should be used with caution in renal insufficiency, but does not require dose adjustment. No changes were seen in renal status, and no renal dose adjustments are necessary when using injectable dulaglutide, lixisenatide, semaglutide, or oral semaglutide. None of these agents cause hypoglycemia when used as monotherapy.

HEPATIC DYSFUNCTION

CASE 53-16

QUESTION 1: B.R., a 60-year-old male with cirrhosis of the liver, is found to have type 2 diabetes. Glipizide 10 mg/day is initiated.

How will B.R.'s liver function affect the disposition of glipizide and his response to this agent?

Most noninsulin antidiabetic agents should be avoided in patients with severe liver disease, and insulin therapy—either basal-bolus or mixed insulin regimens—is often the safest option. Because hepatic metabolism is the primary route of elimination for most sulfonylureas, including glipizide, patients with hepatic disease should be expected to have an exaggerated response to those drugs metabolized to fewer active products. Liver disease can be a separate predisposing factor for severe, prolonged hypoglycemia because glycogenolysis and gluconeogenesis are impaired; thus, sulfonylureas should be avoided in patients with cirrhosis. If they are used, shorter-acting agents are preferred, and small initial doses should be used. For B.R., glipizide could be initiated at a dose no greater than 2.5 mg/day and increased if needed by 2.5-mg increments at no less than weekly intervals. Other options are low doses of repaglinide (0.5 mg) or nateglinide (60 mg) with meals because they are very short acting. Other options for which severe liver disease is not a specific contraindication include GLP-1RAs, DPP-4 inhibitors, and SGLT-2 inhibitors, although generally these drug classes should be avoided in Child–Pugh class C staging.[336]

CASE 53-17

Question 1: J.M. is a frail, 82-year-old, unresponsive male who is brought to the emergency department. According to J.M.'s family, he has become increasingly confused, dizzy, and lethargic, with a recent weight loss of 10 pounds (4.54 kg). J.M. lives by himself and has been generally healthy, with the exception of mild-to-moderate chronic obstructive pulmonary disease and arthritis.

Fasting serum chemistry reveals the following:

Na, 128 mEq/L
Glucose, 798 mg/dL
Serum osmolality, 374 mOsm/L (normal, 280–295 mOsm/kg H_2O)
Blood pH, 7.5
HCO_3, 22

His serum testing returns a negative finding for ketones. On physical examination, J.M. has poor skin turgor and dry mucous membranes and is responsive only to deep pain. His BP is 90/60 mm Hg with a pulse of 96 beats/minute. He has rales at the left lower base of his lung, and a chest

radiograph confirms pneumonia. Despite aggressive fluid replacement, J.M.'s BG remains consistently >250 mg/dL and his A_{1c} is 11%. J.M. presents with very high glucose concentrations but has no history of DM.

What special factors contribute to a late and atypical presentation of diabetes in the elderly?

Diabetes in the Elderly

CLINICAL PRESENTATION

Diabetes in the elderly commonly is underdiagnosed and undertreated because it often presents atypically.[337,338] Classic symptoms associated with DM may be masked by other illnesses, entirely absent, or explained away by the normal aging process. For example, polyuria is minimized by higher renal thresholds for glucose, or it may be confounded by urinary incontinence or "prostate problems." Thirst is commonly blunted in elderly persons, increasing their risk of dehydration and electrolyte imbalance. Hunger can be altered by medications or depression. Fatigue often is discounted as "part of getting old," and weight loss, although sometimes profound, may be so gradual that it goes unnoticed for months to years. (See **Table 53-27** for a comparison of presenting symptoms for DM in elderly patients compared with younger patients.)

Table 53-27

Presentation of Diabetes Mellitus in Elderly Patients Compared With Younger Patients

Metabolic Abnormality	Symptoms in Young Patients	Symptoms in Elderly Patients
Serum osmolality	Polydipsia	Dehydration, confusion, delirium
Glucosuria	Polyuria	Incontinence
Catabolic state owing to insulin deficiency	Polyphagia	Weight loss, anorexia

HYPEROSMOLAR HYPERGLYCEMIC STATE

CASE 53-17, QUESTION 2: J.M. is diagnosed with hyperosmolar hyperglycemic state (HHS). Why are the elderly predisposed to this condition, and what signs and symptoms are consistent with this diagnosis?

HHS is a condition characterized by extremely elevated plasma glucose concentrations (>600 mg/mL) and high serum osmolality (>320 mOsm/L) without ketoacidosis. Because patients with type 2 diabetes have some residual insulin production, they are usually protected against excessive lipolysis and ketone production. Patients with type 2 diabetes may exhibit HHS in later stages of diabetes as loss of β cells becomes advanced and residual insulin production continues to drop.[185] Measurements of serum ketones and blood pH differentiate this condition from DKA (see Case 53-10). The condition occurs when urinary fluid and electrolyte losses secondary to glucosuria are inadequately replaced by oral fluid intake.[185]

HHS primarily occurs in the elderly because several factors predispose this population to hypodipsia. These include an inability to recognize thirst,[339] an inability to ask for fluids (eg, dementia, sedation, and intubation), and an inability to get fluids on demand (eg, physical disabilities or restraints). Infections or other acute illnesses (eg, MI, GI bleeding, or pancreatitis) that exacerbate diabetes can interact with the hyperosmolar diuresis and hypodipsia to produce severe dehydration and hyperglycemia. Drugs that increase plasma glucose concentrations (eg, glucocorticoids), increase diuresis, or decrease mentation also can contribute to this unfortunate situation.

J.M. presents with several symptoms of HHS dehydration, including osmolality >320 mOsm/L, plasma glucose >600 mg/dL, pH >7.3, elevated bicarbonate, decreased skin turgor, hypotension, and the absence of serum ketones. His pneumonia was probably the precipitating factor. Treatment involves rapid IV hydration. Fluid replacement is provided in the same manner as with DKA. See Case 53-10, Question 2, and Table 53-24 for details.[185] Insulin infusion is

given simultaneously. The initiation and rate adjustments are the same as with DKA, except that the plasma glucose cutoff to reduce the insulin infusion rate is 300 mg/dL (not 200 mg/dL as with DKA; see Case 53-10, Question 3, and Table 53-24 for details). Rehydration and insulin administration corrected J.M.'s metabolic imbalance, allowing his diabetes control to be addressed.

GOALS OF THERAPY

Case 53-17, Question 3: What are the goals of therapy for J.M.?

It is widely recognized that strict glycemic control is associated with an increased incidence of hypoglycemia.[33] In the elderly patient with age-related autonomic dysfunction and CVD, hypoglycemia may present without the usual premonitory symptoms and can result in severe adverse effects such as angina, seizures, stroke, or MI. Therefore, the general tendency when treating elderly patients with diabetes is to aim for slightly less aggressive glycemic goals. Thus, an FBG target of between 90 and 150 mg/dL with bedtime glucose values between 100 and 180 mg/dL and an A_{1c} goal of close to 8%, while avoiding hypoglycemia, is appropriate in this frail patient.[340]

DIET AND EXERCISE

Nutrition

Case 53-17, Question 4: How should diet and exercise recommendations be modified for elderly patients with diabetes such as J.M.?

The ADA recommends individualized MNT for all patients with DM. The Dietary Approaches to Stop Hypertension (DASH) diet and Mediterranean diets have been shown to be effective for glycemic control and lowering CVD risk.[54,56,57]

Because most elderly patients have type 2 diabetes, nutrition and exercise programs are the initial steps in therapy. Older people with

diabetes, especially those in a long-term care facility, have a tendency to be underweight rather than overweight.[54,56,57] Therefore, caution should be used when considering a weight loss diet because this could cause malnutrition or dehydration. For obese individuals, a modest weight loss of 5% to 7% may be indicated.[340] However, an involuntary weight gain or loss of >10 pounds (4.54 kg) or 10% of body weight in <6 months should be carefully assessed.[54,56,57]

Several factors can adversely affect proper nutrition in the elderly. They include an impaired ability to shop for and prepare food, limited finances, an age-related decline in taste perceptions, and coexisting illnesses. Ill-fitting dentures, difficulty in chewing and swallowing, and lack of companionship during meals also can contribute to malnutrition as well.

High-fiber diets may lower BG and improve plasma lipids. However, high-fiber diets in frail, elderly patients, particularly those who are bedridden, should be used cautiously because they can be constipating and result in fecal impaction. Ambulatory patients, on the other hand, generally benefit from increased dietary fiber. Because many elderly patients are malnourished, a daily multivitamin preparation containing the recommended daily allowance of each vitamin should be prescribed.[54,56,57]

Exercise

Exercise in the elderly provides all the benefits derived by younger individuals. It increases well-being and glucose stability and may decrease propensity for falls. Exercise also improves BP, lipid profile, hypercoagulability, and bone density. Physical activity is necessary to minimize any lean body mass loss that can occur with caloric restriction. For patients with arthritis, aquatic exercise may be substituted. Before such an exercise program is initiated, careful evaluation is mandatory to avoid myocardial ischemia or the acceleration of retinopathy.

SELECTING AN ANTIDIABETIC AGENT IN THE ELDERLY

CASE 53-17, QUESTION 5: Why is it important to institute drug therapy to treat J.M.'s diabetes? What considerations should be made in selecting an initial treatment regimen?

As in all patients with DM, poor glycemic control increases the risk of long-term complications. Although it is tempting to minimize the importance of glycemic control because these complications take so long to develop, patients such as J.M. may have had unrecognized hyperglycemia for many years before clinical diagnosis. Thus, many have already begun to develop complications. Furthermore, as life expectancy increases, one can expect that these individuals will live long enough to experience morbidity related to diabetes if they are not treated. Therefore, pharmacologic treatment should be considered in J.M.

The general approach to treating an elderly patient with type 2 diabetes is basically the same as that described in Case 53-11, Questions 3, 7, and 8. The initial choice of an antidiabetic agent should be based on the severity of hyperglycemia. Other considerations include body weight, coexisting diseases, and cost of the agent. Patients with IFG (FPG >100, but <126 mg/dL) should be treated with diet and exercise tailored to their individual capabilities. For patients with type 2 diabetes, pioglitazone, SGLT-2 inhibitors, GLP-1 agonists, or DPP-4 inhibitors are all appropriate options as they minimize the risk of hypoglycemia. Sulfonylurea-induced hypoglycemia is a concern in elderly patients. However, if inability to adhere to the multiple daily regimens is problematic, a short-acting sulfonylurea is an appropriate alternative agent. In J.M.'s case, metformin should probably be used in caution because he has chronic obstructive pulmonary disease increasing the risk of hypoxia. Also, he is older than age 80 years and requires an assessment of his eGFR, which is likely diminished. If the eGFR is <30, SGLT-2 inhibitors would not be recommended. GLP-1 agonists are not recommended in patients with a history of pancreatitis or thyroid medullary neoplasia. The favorable effect metformin has on weight is irrelevant in J.M. Thus, although the efficacy of metformin is

comparable to that of sulfonylureas, it is not the agent of first choice for elderly patients such as J.M.[341,342] Patients with an FPG >300 mg/dL and no overt stress should be considered insulin deficient and started on basal insulin therapy.

HYPERTENSION

CASE 53-18

QUESTION 1: L.S. is a 53-year-old, obese male with an 8-year history of type 2 diabetes. His current problems include a BP of 155/103 mm Hg (documented on two occasions), blurry vision, and impotence, which he now admits has troubled him for the past few years. Physical examination reveals decreased pedal pulses bilaterally, loss of sensation to monofilament testing, and evidence of an amputated toe on the right foot. His laboratory values are as follows:

FPG, 170 mg/dL
A_{1c}, 7.8%
Total cholesterol, 240 mg/dL
Triglycerides, 160 mg/dL

L.S. has normal electrolyte values and albuminuria (180 mg/g creatinine). His only medication is metformin 500 mg PO bid. Describe the pathogenesis of hypertension in patients such as L.S.

Why is it so important to treat his hypertension?

Seventy-five percent of adults with diabetes report having a BP of ≥130/80 mm Hg or use medications for hypertension.[343] Hypertension in type 1 diabetes is usually of renal parenchymal origin and occurs 1 to 2 years after the onset of nephropathy as indicated by albuminuria (see Case 53-19, Question 2).[26] The relationship between type 2 diabetes and hypertension is more complex and not as closely correlated to nephropathy. In type 2 diabetes, hypertension is often part of the metabolic syndrome and may be present for years before diabetes is actually detectable.

Patients with diabetes and hypertension have an increased risk for experiencing microvascular complications such as retinopathy and nephropathy. They are also at a twofold increased risk for having CVD.[26] A 5 mm Hg reduction in mean diastolic BP can produce a

37% reduction in microvascular complications, and a 10 mm Hg reduction in mean systolic BP had previously been found to reduce the risk of MI by 11% and death related to diabetes by 15%.[26,301,302] However, because lower BP targets are tested, the benefits are becoming less clear. In the ACCORD BP study, the intensive control arm (achieved systolic BP of 119 mm Hg) did not reduce total CV events (nonfatal MI, nonfatal stroke, or death from CV causes) compared with standard therapy (achieved systolic BP of <133 mm Hg).[9] However, microvascular benefits were observed, as was a statistically significant reduction in stroke. Therefore, the existing ADA BP goal of <140/90 mm Hg is reasonable, and lower goals should not be targeted in practice unless it can be done without adverse effects.[26]

Treatment includes weight management, exercise, sodium restriction (<1500 mg/day), smoking cessation, and antihypertensive therapy. L.S. should be started on an ACEI. ACEIs have traditionally been available as less expensive generics, although angiotensin receptor II blockers (ARBs) are also available and appropriate. Both these agents are recommended in patients with diabetes with concurrent albuminuria and hypertension. Many patients require two or three medications to achieve the target BP goal of <140/90 mm Hg.[26]

NEPHROPATHY

CASE 53-18, QUESTION 2: What is the significance of the presence of albumin in L.S.'s urine? How should it be managed?

Diabetes is the leading cause of ESRD, and it accounted for 44% of new cases of renal failure in 2005.[26,343] Diabetic nephropathy is characterized by nephrotic syndrome and azotemia. It is a major cause of death in patients with type 1 diabetes and is an increasing source of morbidity in individuals with type 2 diabetes.[344] Thickening of the glomerular capillary basement membranes is the hallmark of diabetic nephropathy.[345] Diffuse deposition of basement membrane–

like material expands the mesangium. This process narrows the capillary lumina, impedes blood flow, and thereby reduces the filtering surface area in the glomerulus. Hyperglycemia causes intraglomerular hypertension and renal hyperfiltration. Hyperfiltration is followed by albuminuria with minimal glomerulosclerosis, which still is potentially reversible. If left untreated, overt proteinuria occurs, and the patient usually progresses to nephrotic syndrome. Progression of diabetic renal disease can be accelerated in the presence of hypertension, proteinuria, and diabetic retinopathy. Lipid abnormalities also may contribute to the progression of glomerulosclerosis. Management includes early detection through screening for albuminuria, tight glucose control, use of ACEIs and ARBs for patients with albuminuria (to slow progression), aggressive management of hypertension that includes an ACEI or ARB as first-line therapy,[26] aggressive management of dyslipidemia, and smoking cessation. A thorough discussion on the management of diabetic nephropathy and ESRD is presented in Chapter 28, Chronic Kidney Disease, and of hypertension in people with diabetes, in Chapter 9, Essential Hypertension.

Screening for and confirmation of albuminuria

The preferred method of screening for albuminuria is the measurement of the albumin-to-creatinine ratio in a random spot collection (preferably the first-void or morning sample). Albuminuria is defined as a urinary albumin excretion of ≥30 μg/mg of creatinine (or mg albumin/g creatinine) during a spot collection.[26] Because of day-to-day variability in albumin excretion, two of three urine samples collected in a 3- to 6-month period need to be abnormal before a designation is made. Annual screening should be performed in patients with type 1 diabetes with a duration of at least 5 years and in patients with type 2 diabetes from the time of diagnosis. More frequent screening is indicated if hypertension, any increase in SCr, or retinopathy develops. Urine albumin concentrations can be falsely elevated over true baseline values by

exercise within 24 hours, fever, infection, uncontrolled diabetes, uncontrolled hypertension, and HF.

On the basis of established criteria, L.S. has albuminuria (180 mg albumin/g creatinine). Management includes tight BG control, and an ACEI or ARB should be started (L.S. should already be receiving one of these agents to treat his hypertension as noted). After initiation of therapy, continued periodic monitoring of the albuminuria is recommended to assess the response to therapy and progression of the disease.[26] Serum potassium and creatinine levels should be followed up as well.

CARDIOVASCULAR DISEASE

CASE 53-18, QUESTION 3: L.S. is treated with lisinopril 20 mg/day, which controls his BP and improves his albuminuria. His dose of metformin is titrated to 1000 mg bid. Recent laboratory values include an FPG of 130 mg/dL, A_{1c} of 6.0%, triglyceride level of 170 mg/dL, total cholesterol of 204 mg/dL, LDL-C of 135 mg/dL, and HDL-C of 35 mg/dL. How does the risk of heart disease for patients such as L.S. compare with that for persons without diabetes? What is the pathogenesis of CHD in persons with diabetes?

CHD is the leading cause of premature death in the type 2 population and accounts for 50% of the deaths in people with diabetes. Relative to nondiabetic individuals, those with diabetes are two to three times more likely to develop CHD, and their risk of death after an MI also is two to three times higher than that of their nondiabetic counterparts. Females with diabetes, regardless of their age or menopausal status, have an equal risk for CHD to that of nondiabetic males. These sobering figures point to the importance of minimizing or eliminating all other preventable risk factors for CVD in patients with diabetes (ie, tobacco use, hypertension, hypercholesterolemia, and obesity) through the prescription of exercise, diet, and utilization of medications with known CV benefit.[346]

Pathogenesis

The pathogenesis of CVD in people with diabetes is complex. The metabolic syndrome with its attendant CV risk factors, dyslipidemia, inflammation, and hemostatic abnormalities are only some of the mechanisms under study.[347,348]

The most common lipid abnormality in type 2 diabetes is hypertriglyceridemia (>150 mg/dL) with low levels of HDL-C (<40 mg/dL in males or <50 mg/dL in females), similar to the lipid profile seen in L.S. Poor control of type 1 diabetes also is associated with low levels of HDL-C and a smaller, more-dense LDL particle. These lipid abnormalities, along with a greater prevalence of hypertension, contribute to the risk factors for CVD.

In patients with diabetes, clinical trials of lipid-lowering therapy (primarily with statins) have demonstrated primary and secondary CHD prevention. Although the evidence for the reduction in "hard" CVD outcomes (eg, CHD death and nonfatal MI) is stronger in patients with diabetes who have a high baseline CVD risk (ie, known CVD or very high LDL-C levels), the overall benefits of statins in patients with diabetes at moderate or high risk for CVD are convincing. Readers are referred to the ADA Standards of Medical Care for more detailed information on the CVD clinical trials in patients with diabetes.[26]

DYSLIPIDEMIA

Case 53-18, Question 4: Should L.S. be treated with drug therapy for his dyslipidemia?

The ACC mainly recommends initiating statin therapy based on CV risk. CV risk is determined by age, comorbidities, lipid panel, and social and family history. The ACC/AHA guidelines recommend a moderate-intensity statin for patients with diabetes between the ages of 40 and 75 with LDL between 70 and 189 mg/dL with an estimated 10-year ASCVD risk <20%. A high-intensity statin is recommended for patients with diabetes between the ages of 40 and 75 with LDL between 70 and 189 mg/dL with multiple ASCVD risk factors. The

ACC/AHA further recommends that those patients with diabetes with an estimated 10-year ASCVD risk ≥20% add ezetimibe to maximally tolerated statin therapy to reduce LDL levels by ≥50%. All patients between ages 40 and 75 are recommended a high-intensity statin if they have clinical ASCVD, including CHD, MI, unstable/stable angina, stroke, TIA, or peripheral arterial disease. Patients older than age 75 years are generally recommended to be initiated on a moderate-intensity statin because of the risk of myalgias.[26]

Diet and exercise are cornerstones in the management of dyslipidemia in patients such as L.S. Weight loss is associated with improvements in insulin sensitivity and glucose control, as well as a reduction in triglycerides, total cholesterol, and LDL-C. Physical activity enhances weight loss and increases HDL-C levels. Thus, L.S.'s diet and exercise habits should be reassessed, and instruction in both should be reinforced as appropriate. Because insulin resistance may be the underlying cause of elevated lipids in these patients, efforts should be devoted to reversing insulin resistance as well. Given L.S.'s age (between 40 and 75) and risk factors, he should be prescribed at least a moderate-intensity statin therapy (simvastatin 20–40 mg, atorvastatin 10–20 mg, or rosuvastatin 5–10 mg) to decrease his CV risk.

For a detailed discussion on statin therapy and other lipid-lowering agents, see Chapter 8 (Dyslipidemias, Atherosclerosis, and Coronary Heart Disease).

RETINOPATHY

CASE 53-18, QUESTION 5: L.S. is referred to the ophthalmologist for his persistent vision problems despite improvement in his glycemic control. He is diagnosed with mild background retinopathy. Should L.S. be concerned?

Ocular disorders related to diabetes are the leading cause of new cases of legal blindness in Americans. Patients with diabetes may experience blurred vision associated with poor glycemic control, but retinopathy, senile-type cataracts, and glaucoma are the

complications that threaten sight. Diabetic retinopathy appears as early as 3 years after diagnosis and is evident in 90% of individuals with type 1 diabetes after 15 years. Comparable figures for patients with type 2 diabetes treated with insulin and for those treated with diet and oral agents are 80% and 55%, respectively. Proliferative retinopathy is less prevalent but nevertheless is present in 30% of people with type 1 diabetes and in 10% to 15% of insulin-treated patients with type 2 diabetes who have had diabetes for 15 years or longer.[349]

Patients with type 1 diabetes should have a dilated retinal examination within 5 years of diagnosis; evaluation is not necessary before 10 years of age. Patients with type 2 diabetes should have a comprehensive eye examination soon after diagnosis. The ADA recommends annual comprehensive eye examinations.[26] Less-frequent eye examinations (every 2–3 years) can be considered in patients with normal examinations based on the advice of an ophthalmologist.[349]

Current theories addressing the possible causes of this complication have been thoroughly reviewed.[349] Microvascular disease characterized by thickening of the capillary membrane may be the underlying lesion for two forms of retinopathy. The first and most common presentation is a nonproliferative retinopathy, which is characterized by microaneurysms that may progress to hard, yellow exudates, signifying chronic leakage, retinal edema, and punctate hemorrhage. This form of retinopathy may be associated with loss of central vision, but generally is associated with an excellent visual prognosis. Focal laser photocoagulation of the retina in patients with nonproliferative diabetic retinopathy and macular edema decreases the likelihood of visual loss by 50%.[26]

A second, less common presentation is proliferative retinopathy. This form is characterized by neovascularization (presumably owing to retinal hypoxia). Neovascularization ultimately leads to fibrosis, vitreous hemorrhage, and retinal detachment. Photocoagulation therapy may arrest progression and decrease the loss of vision associated with neovascularization.[349] Because hypertension, smoking, uremia, and hyperglycemia may lead to more rapid

progression of the retinopathy, every effort should be made to eliminate these risk factors for L.S.

The ACCORD study assessed the impact of intensive glycemic, BP, and lipid control on the progression of retinopathy.[350] After 4 years, the rates of progression of diabetic retinopathy were reduced with intensive glycemic control (7.3% vs 10.4% with standard therapy) and also with fenofibrate (6.5% vs 10.2% with standard therapy of just a statin alone). Somewhat surprisingly, intensive BP control did not have an effect (10.4% vs 8.8% with standard therapy). However, on closer interpretation, this finding makes sense because the BP in the standard therapy group achieved excellent control (133.5 mm Hg), so further lowering the BP (119.3 mm Hg in the intensive group) did not provide additional benefit in reducing the rate of retinopathy progression (see Case 53-19, Question 1).

Case 53-18, Question 6: Should L.S. be started on aspirin therapy?

The issue of aspirin use for primary prevention continues to be debated. The ADA recommends aspirin therapy as secondary prevention in patients with a documented history of ASCVD (eg, MI, vascular bypass procedure, peripheral vascular disease, stroke or transient ischemic attack, claudication, or angina). Primary prevention is indicated in individuals with diabetes who have a significant risk of CVD events (10-year risk >10%). Although the ADA lists several risk calculators that can be used in patients with diabetes, the UKPDS calculator can be downloaded and is relatively easy to use (http://www.dtu.ox.ac.uk/riskengine/).[351]

According to the ADA guidelines, aspirin therapy (75–162 mg/day) may be considered for primary prevention in patients with diabetes who are at increased CV risk, after a comprehensive discussion with the patient on the benefits versus the comparable increased risk of bleeding. Recommendations for using aspirin as primary prevention include both males and females ages 50 years with diabetes and at least one additional major risk factor (family history of premature ASCVD, hypertension, dyslipidemia, smoking, or CKD/albuminuria)

who are not at increased risk of bleeding (eg, older age, anemia, or renal disease).

In patients (with or without diabetes) older than age 70, aspirin may pose more of a risk than a benefit. Therefore, aspirin can be considered but is generally not recommended in this patient population.

AUTONOMIC NEUROPATHY: GASTROPARESIS

CASE 53-19

QUESTION 1: H.D. is a 36-year-old male with a 20-year history of type 1 diabetes. He has poor glycemic control (A_{1c}, 12%) and frequent, severe hypoglycemic reactions that "don't make sense." According to H.D., "I have insulin reactions right after I eat, but later on, my glucose concentrations are sky high." H.D. presents to the diabetes clinic with a 2-month history of nausea, postprandial fullness, early satiety, and occasional vomiting, all of which are unrelieved by antacids. H.D. also has peripheral neuropathy involving both his hands and feet and manifestations of autonomic neuropathy (impotence and orthostatic hypotension). An upper GI series was ordered to rule out peptic ulcer disease and gastroesophageal reflux disease, and a solid-meal, gastric emptying study using scintigraphy indicates the diagnosis of diabetic gastroparesis.

What is the cause of diabetic gastroparesis? How should H.D. be treated?

Autonomic neuropathy may present as gastroparesis with feelings of bloating and nausea, urinary retention, impotence in males (manifested as retrograde ejaculation or an inability to attain an erection), postural hypotension, tachycardia, and diarrhea with incontinence of stool.[352] The presence of autonomic insufficiency may have profound effects on the patient's response to vasodilating drugs and ability to counteract hypoglycemia.

Poor glycemic control with "unexplained" hypoglycemia may result from the disrupted delivery of food to the intestine; that is, glucose delivery does not correspond with prandial insulin action. As a result, the BG levels can fluctuate greatly. Many patients with diabetic gastroparesis, such as H.D., have had diabetes for many years and also have evidence of peripheral and autonomic neuropathies.

Conventional antiemetic therapy is usually not helpful in the treatment of gastroparesis. Prokinetic agents, such as metoclopramide, are considered first-line therapy.[353] Metoclopramide increases gut motility through indirect cholinergic stimulation of the gut muscle. However, symptomatic improvement does not always correlate with improved gastric emptying, which implies that the effectiveness of metoclopramide also is related to its centrally mediated antiemetic activity. A usual starting dose of metoclopramide is 10 mg orally four times daily (qid), 30 minutes before meals, and at bedtime. Patients should be monitored for tardive dyskinesia, a potentially irreversible and disfiguring condition that is characterized by involuntary movements of the tongue, face, or extremities. In 2009, the FDA added tardive dyskinesia as a black box warning for metoclopramide.[354] The risk of tardive dyskinesia increases with the duration of treatment and the total cumulative dose.

Other pharmacotherapeutic interventions include domperidone (not available in the United States), cisapride (withdrawn from the U.S. market), erythromycin, and cholinergic agonists.[353] A key component to treating H.D.'s gastroparesis is improving his glycemic control. Also, H.D. should be advised to try eating smaller, more frequent meals and to chew his food well; this of course will require adjustments to his prandial insulin therapy. Also, eating a low-fiber and low-fat diet may help with his symptoms.[353]

PERIPHERAL NEUROPATHY

CASE 53-19, QUESTION 2: Six months after institution of metoclopramide 10 mg qid and several insulin adjustments, H.D.'s GI symptoms have been alleviated, and his diabetes is now reasonably well controlled, as evidenced by elimination of hypoglycemic episodes and a recent A_{1c} of 7.5%. However, H.D. has increasing bilateral foot pain, which he describes as a burning, tingling, or prickly sensation. An examination of his feet reveals cool extremities with absent pulses, reduced vibration perception, and loss of 10-g monofilament pressure sensation. What are appropriate steps that can be taken to alleviate H.D.'s peripheral neuropathy?

Diabetic neuropathy may be a consequence of metabolic disturbances in the neurons, microangiopathy affecting the capillary supply to neurons, or an autoimmune process. It affects 60% to 70% of the diabetic population and has a broad spectrum of presentation. Clinically, it most commonly presents as a diffuse symmetric sensorimotor syndrome, as carpal tunnel syndrome, or as autonomic neuropathy (eg, tachycardia or orthostatic hypotension caused by CV autonomic neuropathy). Symptomatic diabetic peripheral neuropathy occurs in 25% of patients with diabetes. It is characterized by paresthesia and pain in the lower extremities that may be mild or severe and unrelenting, decreased sensation to monofilament testing, decreased ankle and knee jerks, and decreased nerve conduction velocity. The decreased sensation associated with peripheral neuropathy contributes to the progression of foot injuries and infections that may go unnoticed by the patient until they are severe. The management of diabetic neuropathies has been reviewed.[26,355,356] To view a video of how to perform a complete foot examination, see http://www.medscape.com/viewarticle/708703.

Pharmacologic management consists of symptomatic therapies. Painful neuropathy may respond to simple analgesics (eg, acetaminophen) or nonsteroidal anti-inflammatory drugs. The analgesic selected should be based on the patient's history of responsiveness to these agents and their duration of action and side effect profiles. Analgesics such as acetaminophen, when overused, can lead to hepatotoxicity. Avoid chronic nonsteroidal anti-inflammatory drug use owing to their renal toxicity, bleeds, and development of GI ulcers. Other pharmacologic options include tricyclic antidepressants (TCAs), duloxetine (a serotonin and norepinephrine reuptake inhibitor), gabapentin, pregabalin, and other anticonvulsants (carbamazepine, lamotrigine, topiramate, and oxcarbazepine). Only pregabalin and duloxetine have the FDA indication for the treatment of diabetic peripheral neuropathy (DPN); others are off label (ie, gabapentin). Efficacy, side effects, drug interactions, renal and hepatic function, and cost should all be considered when an agent is chosen. Often less expensive options are tried first, off label such as gabapentin or a TCA.[357-359]

Topical application of 0.075% capsaicin has been recommended for diabetic neuropathy, but may take several weeks to work. Lidocaine 5% patches have also been used. These may be helpful in patients intolerant to oral medications. These may be used in combination with oral medications. Tramadol or opiates may also be used as a second line.[357-359]

CASE 53-19, QUESTION 3: Can anything be done for H.D.'s peripheral vascular disease?

Peripheral vascular disease or peripheral arterial disease presents as diminished or absent foot pulses, intermittent claudication, skin ulcers, gangrene, or amputation. People with diabetes are 2 to 10 times more likely to experience symptoms of peripheral arterial disease than are those without diabetes, and half of all nontraumatic amputations in the United States are performed in patients with diabetes. In one study that followed type 2 patients for 7 years, 5.5% had an amputation. The prevalence of this condition increases with age, duration of diabetes, and the presence of risk factors such as hypertension or smoking.[356,360]

Signs and symptoms of peripheral arterial disease include leg pain, which is relieved by rest; cold feet; nocturnal leg pain, which is relieved by dangling the feet over the bed or walking; absent pulses; loss of hair on the foot and toes; and gangrene. Treatment of this condition includes elimination and treatment of risk factors such as smoking, dyslipidemia, hypertension, and hyperglycemia; antiplatelet therapy; exercise, which is the mainstay of therapy; and revascularization surgery.[360] H.D. should be thoroughly educated regarding proper foot care, perform daily self-foot examinations, and receive regular care by a podiatrist.[361]

DRUG-INDUCED ALTERATIONS IN GLUCOSE HOMEOSTASIS

Persons with diabetes are likely to take more drugs in their lifetime than do any other group of patients. Patients with type 2 diabetes present with a constellation of chronic conditions, including hypertension, dyslipidemia, and CVD, all of which will likely require drug therapy. Drugs to manage depression, intermittent infections, and neurologic and ophthalmologic conditions also are commonly prescribed. Because we know that the actions of drugs are complex and that for every desired effect there are several other unwanted effects, each time a drug is added to the regimen of someone with diabetes, it is important to assess the patient's situation to determine whether a potential exists for a drug–drug or drug–disease interaction or whether the benefit of the newly prescribed drug is likely to outweigh its risks. With the availability of online drug information databases to assist in the assessment of drug–drug and drug–disease interactions, a detailed listing of drugs that can exacerbate hyperglycemia and hypoglycemia is not provided. But a few case examples are illustrated here. Some medications that can have significant hyperglycemic effects include atypical antipsychotics, protease inhibitors, corticosteroids, immunosuppressants (eg, tacrolimus and cyclosporine), niacin (higher doses), gonadotropin-releasing hormone agonists (used in males for prostate cancer), and pentamidine (can also cause hypoglycemia).[362,363] Patients should be monitored closely for a medication's possible effect on the BG levels.

Drug-Induced Hyperglycemia

CORTICOSTEROIDS

CASE 53-20

Question 1: A.L., a 37-year-old obese female with systemic lupus erythematosus, has been taking 60 mg/day of prednisone for 6 months. During this period, her weight has increased by 30 pounds (13.61 kg) and she has experienced glycosuria (no ketones). Her primary provider asked her to start SMBG. She was referred to the diabetes clinic, where her predinner and bedtime BG values were found to be 140 to 160 mg/dL and FBG values were

80 to 105 mg/dL. Physical examination shows a 62 inches (157.48 cm), 150-pounds (68.04 kg), depressed female with truncal obesity and an acneiform rash. Her mother and one sister have type 2 diabetes.

How do corticosteroids contribute to DM? How should A.L. be treated?

The term *steroid diabetes* was first used to describe the hyperglycemia and glycosuria seen in patients with Cushing syndrome. Now, it is associated more commonly with exogenously administered glucocorticoids and has been a side effect of parenteral, oral, and even topical therapy. Corticosteroids are one of the most common drug groups that unmask latent diabetes or aggravate preexisting disease, and they may produce hyperglycemia and overt diabetes in individuals who are not otherwise predisposed.

Corticosteroids increase hepatic gluconeogenesis, suppress insulin secretion, and decrease tissue responsiveness to insulin.[363] The primary effect is impaired glucose disposal after meals, resulting in daytime hyperglycemia, and by morning, the glucose levels normalize. Although steroid-induced diabetes generally is mild and rarely associated with ketonemia, a wide spectrum of severity may be encountered—from asymptomatic, abnormal glucose tolerance tests to difficult-to-control, insulin-requiring disease. The onset of glucose tolerance can occur within hours to days or after months to years of chronic therapy. The effect generally is considered dose dependent and usually is reversible on discontinuation of the drug.

A.L. exhibits many symptoms that can be attributed to supraphysiologic doses of corticosteroids: truncal obesity, depression, acneiform rash, and diabetes. Mildly elevated glucose levels in obese individuals, as in A.L.'s case, sometimes can be controlled by diet but may require treatment with a short-acting insulin secretagogue or rapid-acting insulin before meals.[363] A person with diabetes whose BG is increased by the use of a glucocorticoid should modify treatment appropriately to restore glycemic control. It is important to anticipate the need to modify insulin or other antidiabetic therapy because corticosteroid doses are increased or decreased.

SYMPATHOMIMETICS

CASE 53-21

QUESTION 1: R.C., a 41-year-old male with type 1 diabetes, is well controlled on a basal-bolus insulin regimen and has been taking pseudoephedrine 30 mg qid for 7 days and Robitussin DM 10 mL qid (which contains 2.92 g of sugar/5 mL) for a cold. Recently, glucose concentrations have been higher than usual.

Can pseudoephedrine or the cough preparation be the cause of his poor glycemic control? How can sympathomimetics and cough preparations affect patients with diabetes?

Over-the-counter drug products, such as decongestants and diet aids, which contain sympathomimetics, carry warning labels that caution against their use in patients with diabetes. Standard sugar- and ethanol-containing cough preparations also carry such warning labels. However, clinically significant drug-induced glucose intolerance probably is very infrequent. It is well established that parenterally administered epinephrine increases BG concentrations secondary to increased glycogenolysis and gluconeogenesis. Other sympathomimetics generally do not have as potent an effect on BG as does epinephrine, and their use usually does not pose a practical problem in patients with diabetes. Furthermore, the effects of sympathomimetics on BP must be considered in many patients with diabetes. Therefore, antihistamines or occasional use of nasal sprays for severe congestion may be needed.

In summary, pseudoephedrine or the cough preparation may be aggravating R.C.'s glycemic control, although at these low-to-normal therapeutic doses, it is quite unlikely. The stress related to R.C.'s underlying cold is more likely to be impairing his glucose tolerance than do these low doses of sympathomimetic agents or the small amounts of sugar contained in the cough syrup.

Drug-Induced Hypoglycemia

ETHANOL

CASE 53-22

QUESTION 1: C.F., a 22-year-old female with newly diagnosed type 1 diabetes, enjoys a glass or two of wine with her evening meal.

What effect does alcohol have on a patient with diabetes, particularly one using insulin? Is alcohol contraindicated in C.F. or any person with diabetes?

Clinicians often are reluctant to permit the use of alcoholic beverages in patients with diabetes. However, barring contraindications that are similar in the nondiabetic individual and patient with diabetes alike (eg, alcoholism, hypertriglyceridemia, gastritis, pancreatitis, and pregnancy), a person with diabetes can safely enjoy a moderate alcohol intake as long as certain precautions are taken. For an in-depth discussion, the reader is referred to two comprehensive reviews of alcohol and diabetes,[364,365] parts of which are summarized in the following list:

- Drink in moderation: The ADA defines this as a daily intake of one drink for adult females and two drinks for adult males (one drink is defined as 5 ounces of wine, 12 ounces of beer, or 1.5 ounces of distilled liquor). The patient should be aware of his/her own sensitivity to the intoxicating effects of ethanol and adjust consumption downward, if needed. This is particularly important for insulin-dependent patients. When having a drink, be sure to have it with a carbohydrate-containing meal.
- Avoid drinks that contain large amounts of sugar: Instead of drinks such as liqueurs, sweet wines, and sugar-containing mixes, consider dry wines, light beers, and distilled spirits. Not only does the simple sugar content add an additional source of glucose and calories to the diet but ethanol ingested with simple sugar-containing mixers also enhances reactive hyperglycemia.
- Remember to count the calories in alcohol: Instead of (calories – [0.8] × [proof] × [ounces]); substitute 1 ounce of alcohol for two fat exchanges.
- Be aware that the symptoms of alcohol intoxication and hypoglycemia are similar: If hypoglycemia is mistaken for

intoxication by others, appropriate and potentially life-saving treatment can be delayed.

- Be aware of alcohol–sulfonylurea drug interactions: and, specifically, the alcohol-induced enzyme induction of tolbutamide metabolism and the chlorpropamide–alcohol flush reaction.

Eye Disorders

Section Editor: Susan Jacobson

54

Eye Disorders

Katherine Carey and Bridget C. Hendricks

CORE PRINCIPLES		CHAPTER CASES
GLAUCOMA		
1	There are different types of glaucoma, including open-angle glaucoma and angle-closure glaucoma. Angle-closure glaucoma is a medical emergency requiring immediate intervention. Open-angle glaucoma is a chronic condition, which can result in progressive loss of vision leading to blindness if left untreated.	**Case 54-1 (Question 1) Case 54-2 (Question 1)**
2	Treatment for open-angle glaucoma is targeted toward reducing intraocular pressure (IOP), a clinical measure of drug efficacy. Prostaglandin analogs (PGAs), β-adrenergic blockers, and α-	**Case 54-1 (Question 2-7), Figure 54-1, Table 54-1**

	adrenergic agonists are the mainstay of treatment. Treatment is not curative.	
	OCULAR AND SYSTEMIC SIDE EFFECTS OF DRUGS	
1	Many widely used medications for various conditions cause ocular side effects. The true incidence is frequently not known, making the reporting of ocular side effects of drugs an important function for any health care practitioner.	**Case 54-3 (Question 1), Table 54-3**
2	Conversely, many topically administered ocular medications may cause systemic symptoms.	**Case 54-10 (Question 1)**
	OCULAR EMERGENCIES	
1	Ocular emergencies like chemical burns, corneal trauma, corneal ulceration, acute angle closure glaucoma, and gonococcal conjunctivitis require immediate referral to the emergency department or an ophthalmologist.	**Case 54-4 (Question 1), Case 54-7 (Question 1)**
	COMMON OCULAR DISORDERS	
1	Dry eye disease (keratoconjunctivitis sicca) is a common ocular disorder involving chronically reduced tear film and inflammation of the ocular surface. There are a wide array of treatments, including tear replacement and anti-inflammatory therapies.	
2	Stye (hordeolum) is a common ocular disorder for which no viable over-the-	

	counter (OTC) treatment exists.	
3	Conjunctivitis (pinkeye) is frequently related to bacterial or viral infection, or allergy. Viral conjunctivitis is generally self-limiting. Bacterial conjunctivitis should be treated with an appropriate antimicrobial, recognizing that Gram-positive organisms are frequently the cause. A number of agents are available for the treatment of allergic conjunctivitis. Among those, decongestants (eg, tetrahydrozoline) should be used for no >72 hours, because they may mask a more serious condition or result in rebound redness.	**Case 54-5 (Question 1), Case 54-6 (Question 1)**
	CORTICOSTEROIDS	
1	Topical corticosteroids are used for a variety of ocular inflammatory conditions. The most potent topical corticosteroid is prednisolone acetate 1%.	**Case 54-8 (Question 1), Table 54-4**
2	Topical and oral corticosteroids may be associated with serious side effects, such as increases in IOP and cataracts (with long-term use).	**Case 54-8 (Questions 1,2) Case 54-9 (Question 1), Table 54-5**
	OCULAR HERPES SIMPLEX VIRUS INFECTIONS	
1	Ocular herpes is common and may be caused by herpes simplex virus or, less commonly, varicella-zoster virus. Treatment options include trifluidine, acyclovir, ganciclovir, and cidofovir.	**Case 54-12 (Question 1)**

AGE-RELATED MACULAR DEGENERATION

1	There are two forms, non-neovascular (affecting 80% of patients) and, the more serious form, neovascular (affecting 20% of patients).	**Case 54-13 (Question 1)**
2	Neovascular macular degeneration is associated with abnormal growth of blood vessels behind the retina (choroidal neovascularization) and may be treated by vascular endothelial growth factor (VEGF) inhibitors.	**Case 54-13 (Question 1)**

INTRODUCTION

The eye is a highly complex organ composed of various parts, all of which must function in integration to permit vision. A brief overview of the anatomy and physiology of the eye prefaces the presentation of specific eye disorders. Readers should consult an ophthalmology textbook for an understanding of ocular anatomy, physiology, and general ophthalmology (eg, *Vaughan and Asbury's General Ophthalmology*).[1]

OCULAR ANATOMY AND PHYSIOLOGY

The eyeball is ~1 inch wide and is housed in a cavity (ie, eye socket) formed by two bony orbits that are lined with fat, which serves to protect the eyeball. Six ocular muscles facilitate movement of the eyeball (**Fig. 54-1**).

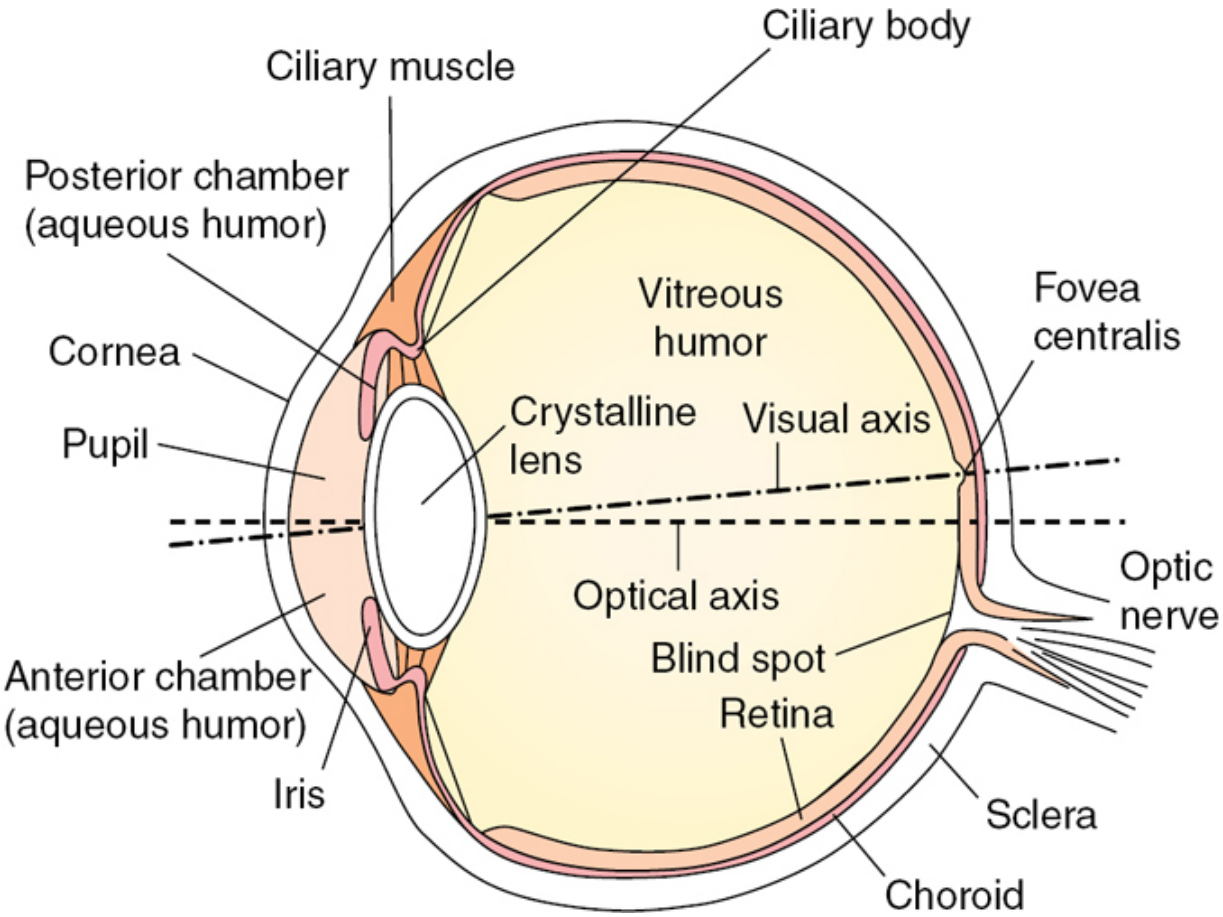

Figure 54-1 Anatomy of the human eye. (Adapted from http://commons.wikimedia.org/wiki/File:Eyesection.svg.)

The outer coat of the eye is made up of the sclera, conjunctiva, and cornea. The *sclera* is the white, dense, fibrous protective coating. The *episclera*, a thin layer of loose connective tissue, contains blood vessels that cover and nourish the sclera. The *conjunctiva* is a mucous membrane that covers the anterior portion of the eye and lines the eyelids. The *cornea* is the transparent, avascular tissue that functions as a refractive and protective window membrane through which light rays pass en route to the retina.

The corneal epithelium and endothelium are lipophilic, and the centrally located stroma is hydrophilic. These three corneal layers are particularly important because they affect drug penetration through the cornea. Ophthalmic medications, which are both fat and water soluble, are best able to penetrate through the intact cornea.

The iris, choroid, and ciliary body are known collectively as the uveal tract. The *iris* is a colored, circular membrane suspended between the cornea and the crystalline lens. It controls the amount of light that enters the eye. The *choroid*, located between the sclera and the retina, is largely made up of blood vessels, which nourish the retina. The *ciliary body* is adherent to the sclera and contains the ciliary muscle and ciliary processes. The ciliary muscle contracts and relaxes the zonular fibers, which hold the crystalline lens in place. The ciliary processes are responsible for the secretion of aqueous humor, a clear liquid that occupies the anterior chamber. The anterior chamber is bounded anteriorly by the cornea and posteriorly by the iris. The posterior chamber lies between the iris and the crystalline lens.

The inner segment of the eye contains the retina with the optic nerve. The *retina*, the light-sensitive tissue at the back of the eye, contains all of the sensory receptors for light transmission. The *optic nerve*, a bundle of more than a million nerve fibers, transmits visual impulses from the retina to the brain.

The crystalline lens, aqueous humor, and vitreous humor assist the cornea with the refraction of light. The *lens*, located behind the iris, functions to focus light onto the retina by changing its shape to accommodate near or distant vision. The innermost part of the lens (ie, the nucleus) is surrounded by the softer material of the cortex. The *aqueous humor*, the thin watery fluid that fills the anterior chamber (ie, the space between the cornea and the iris) and posterior chamber of the eye, functions to provide nourishment to the cornea and lens. Disorders involving the aqueous humor are presented in the section on glaucoma. The primary function of the *vitreous humor* (ie, the jellylike substance between the lens and the retina) is to maintain the shape of the eye and allow the transmission of light to the retina.

The eyelids and eyelashes are the outermost means of protection for the eye. The eyelids contain various sebaceous and sweat glands, which may become infected or inflamed, contributing to many ocular disorders.

The eye is innervated by both the sympathetic and parasympathetic nervous systems. Parasympathetic fibers, originating from the oculomotor nerve in the brain, innervate the ciliary muscle and sphincter pupillae muscle that constrict the pupil. As a result, parasympathomimetic (cholinergic) medications generally are associated with *miosis* (pupillary contraction), and parasympatholytic (anticholinergic) agents are associated with *mydriasis* (pupillary dilation) and *cycloplegia*. The term *cycloplegia* refers to a paralysis of the ciliary muscle and zonules (fibrous strands connecting the ciliary body to the lens) that results in decreased accommodation (adjustment of the lens curvature for various distances) and blurred vision. Tear secretion by the lacrimal glands is also a parasympathetic function.

Sympathetic fibers from the superior cervical ganglion in the spinal cord innervate the dilator pupillae muscle, the blood vessels of the ciliary body, the episclera, and the extraocular muscles. Sympathomimetics cause mydriasis without affecting accommodation.

In this chapter, we discuss glaucoma and other common ocular disorders, such as ocular infectious conditions, ocular inflammatory conditions, dry eye syndrome, age-related macular degeneration (AMD), as well as ocular and systemic side effects of drugs. The conditions discussed are all common conditions that the pharmacist may encounter in all practices of pharmacy. It is important for the pharmacist to be educated on these disorders and their associated treatment so that the pharmacist can evaluate the appropriateness of pharmacotherapy, screen for adverse effects and drug interactions, and counsel patients on their ocular medications.

GLAUCOMA

Glaucoma is the leading cause of irreversible blindness worldwide. The estimated number of suspected cases worldwide is 76 million and that number is expected to increase to 111 million in 2040. In the

United States, an estimated 3 million Americans are living with glaucoma, but only half know they have it.[2] Glaucoma is a general term used for a group of diseases that can irreversibly damage the optic nerve. The nerve damage presents as optic neuropathy with a characteristic “cupping” or excavation of the optic disc. Damage to the nerve results in corresponding visual field loss. Increased intraocular pressure (IOP) is one of the most common risk factors for the development of glaucoma. Generally, the higher the IOP, the greater the risk for developing glaucoma. However, there are forms of glaucoma that can develop in people with normal IOP. Increasing age, race (African descent), family history, thinner central corneas, and larger vertical cup-to-disc ratios are other risk factors for glaucoma.[1,3,4]

Intraocular Pressure

IOP is maintained by the balance between production of aqueous humor by the ciliary processes and the outflow of aqueous humor through the trabecular meshwork and uveoscleral outflow pathway. A test called *tonometry* can indirectly measure the IOP based on the pressure required to flatten a small area of the central cornea. Goldmann Applanation tonometry is the gold-standard method of determining IOP in a glaucoma evaluation. Generally, an IOP of 10 to 21 mm Hg is considered normal. An IOP of 22 mm Hg or greater poses an increased risk of glaucoma, although one of the less prevalent forms of glaucoma is associated with a low-to-normal IOP. IOP alone is not sufficient to rule in or rule out glaucoma. A thorough analysis of risks and comprehensive ocular health examination is necessary in order to diagnose glaucoma.[5]

Ocular Hypertension

Although elevated IOP poses a significant risk for glaucoma, it is possible to have elevated IOPs and not have glaucoma. This is referred to as *ocular hypertension*. Ocular hypertension is defined as

an IOP exceeding 21 mm Hg with normal visual fields, normal optic discs, open angles, and the absence of any ocular disease contributing to the elevation of IOP. Ocular hypertension is sometimes treated prophylactically with IOP-lowering medications, as it poses an increased risk for the development of glaucoma. Patients with normal visual fields and IOPs of 24 mm Hg or greater have a 10% likelihood of developing glaucoma in 5 years.[6,7] Patients with ocular hypertension are monitored closely, and a diagnosis of glaucoma can be applied when pathologic cupping of the optic nerve and/or a defect in the visual field is observed.[8]

Open-Angle Glaucoma

Primary open-angle glaucoma (POAG) is glaucoma in the presence of open anterior chamber angles and in the absence of other known causes of glaucomatous disease. Similar to other forms of glaucoma, it manifests by cupping (ie, excavation) of the optic disc and corresponding visual field loss. POAG occurs in ~2% of people older than 40 years in the United States. However, it can affect other age groups, including children.[1,3,4] In patients with POAG, aqueous humor outflow from the anterior chamber is continuously subnormal, primarily because of a degenerative process in the trabecular meshwork. Owing to diurnal variation, the IOP can fluctuate during the course of a day from normal to significantly high pressures.[1] The decreased outflow appears to be caused by degenerative changes in outflow channels (ie, the trabecular meshwork and Schlemm canal) and tends to worsen with the passage of time.[1] In rare cases, the outflow is normal even during a phase of elevated IOP, and the elevation appears to be the result of hypersecretion of aqueous humor.[1]

The onset of POAG is usually gradual and asymptomatic. A defect in the visual field (ie, scotoma) may be present in early glaucoma, but noticeable loss of peripheral vision is usually not seen until late in the course of the disease. Visual field defects correlate well with changes in the optic disc and help differentiate glaucoma from ocular

hypertension in patients with increased IOP. In addition, the characteristic pattern of visual field loss seen in glaucoma can help differentiate it from other nonglaucomatous forms of optic neuropathy.[9]

Angle-Closure Glaucoma

Examination of the anterior chamber angle by gonioscopy, using a corneal contact lens, a magnifying device, and a light source (eg, a slit-lamp biomicroscope), assists in differentiating between open-angle glaucoma and *angle-closure glaucoma*. Angle-closure glaucoma accounts for ~10% of all primary glaucoma cases in the United States. However, the prevalence is higher in Asian populations, in which 50% of glaucoma cases are angle closure.[10] The sole cause of the elevated IOP in angle-closure glaucoma is blockage of the anterior chamber angle, causing aqueous humor to build up in the anterior chamber, leading to an increase in IOP.[1,7]

Angle-closure glaucoma, which is a medical emergency in the acute form, usually presents as a rapid increase in IOP, blurring or sudden loss of vision, appearance of haloes around lights, and pain that is often severe. When patients are predisposed to angle-closure glaucoma, their pupils should not be dilated (eg, during an ophthalmic examination) and they should be taught the signs and symptoms of angle closure. Acute attacks can sometimes terminate without treatment, but if the IOP remains high, the optic nerve can be irreparably damaged.[1] Patients with chronic angle-closure glaucoma generally experience a gradual closure of aqueous humor outflow channels, and patients may remain asymptomatic until the glaucoma is in an advanced stage.[1] Permanent medical management of acute or chronic angle-closure glaucoma can be difficult: surgical procedures (eg, peripheral iridectomies) are typically indicated as the definitive treatment and are often used in conjunction with medical treatment.

Therapeutic Agents for Treatment of Primary Open-Angle Glaucoma

INITIAL THERAPY

The goals of medical treatment of POAG are to obtain 24-hour IOP control with minimum concentration of medications, minimum number of medications, and minimal local and systemic side effects.[8] Major drug classes for medical treatment of POAG include the following: α-agonists, β-adrenergic blockers (β-blockers), carbonic anhydrase inhibitors (CAIs), miotic agents, nitric oxide (NO) donors, prostaglandin analogs (PGAs), and rho-kinase (ROCK) inhibitors. PGAs are the most commonly prescribed first-line agents for POAG due to their increased efficacy and decreased dosage schedule. β-Adrenergic blockers are another first-line treatment option, although, in recent years, they have become more commonly used as a second-line or adjunctive treatment option. All of the ophthalmic β-blockers currently on the market are available in generic formulation, allowing for cost-effective treatment. Some of the PGAs are available as generic formulations as well, making their cost comparable to β-blockers. NO donors and ROCK inhibitors are newer agents, which can be very effective treatment options when traditional treatments have failed or are contraindicated.[11]

Prostaglandin analogs

Latanoprost (Xalatan®), travoprost (Travatan Z), bimatoprost (Lumigan®), and tafluprost (Zioptan®) are all PGAs. Latanoprost, travoprost, and tafluprost are analogs of prostaglandin $F_2\alpha$, and they lower IOP by serving as selective prostaglandin $F_2\alpha$-receptor agonists. Bimatoprost is a synthetic prostamide analog. Tafluprost is a preservative-free formulation supplied in single-use containers.[12]

The PGAs increase uveoscleral outflow of aqueous humor and thereby decrease IOP.[13] These agents are often prescribed as the

first-line agents for the treatment of POAG because they have been shown to be more effective than β-blockers, can be administered once a day, and are associated with minimal systemic adverse effects. On average, PGAs decrease IOP by 25% to 35% depending on the strength used.

Latanoprost

Latanoprost (Xalatan®) is approved for the initial treatment of POAG or ocular hypertension.[14] When administered once daily in the evening, the IOP-lowering effects of latanoprost have been shown to be superior to those of timolol 0.5% twice daily (bid).[15,16] In addition, the nocturnal control of IOP with latanoprost was superior to that with timolol. Latanoprost should be dosed only once daily in the evening because the IOP-lowering effects of latanoprost might actually be inferior when administered more frequently. Overdosing of latanoprost can in fact cause a paradoxical rise in IOP.

Systemic side effects are minimal with latanoprost, but local reactions (eg, iris pigmentation; eyelid skin darkening; periorbital fat atrophy resulting in deepening of superior lid sulcus with ptosis and enophthalmos; eyelash lengthening, thickening, pigmentation, and misdirected growth; conjunctival hyperemia; ocular irritation; and superficial punctate keratitis) are relatively common. Latanoprost can gradually increase the amount of brown pigment in the iris by increasing the melanin content in the stromal melanocytes of the iris. This pigment change occurs in 7% to 22% of patients and is most noticeable in those with green-brown, blue/gray-brown, or yellow-brown eyes.[14] The onset of increased iris pigmentation is usually noticeable within the first year of treatment and can be permanent.

Latanoprost has additive effects when administered with β-blockers (eg, timolol), CAIs (eg, dorzolamide), and α_2-adrenergic agonists (eg, brimonidine, apraclonidine). When added to existing therapy, latanoprost decreases IOP an additional 2.9 to 6.1 mm Hg. As a result, latanoprost is a good adjunctive ophthalmic agent for patients who are unable to adequately lower their IOP with single-agent therapy. The effectiveness of latanoprost when used once a

day either alone or as an adjunct to other IOP-lowering drugs and its relative tolerability makes it one of the most common, if not, treatment option for POAG and ocular hypertension.[15–20]

Travoprost

Travoprost (Travatan Z) is U.S. Food and Drug Administration (FDA) approved for the reduction of elevated IOP and ocular hypertension in patients who are intolerant or who fail to respond to other agents. Travoprost is often used as a first-line agent in clinical practice because it is more effective than timolol and at least as effective as latanoprost. In addition, it has been shown to be more effective than other PGAs in African Americans. The mean IOP reduction with travoprost in African American patients was 1.8 mm Hg greater than in non–African American patients. Travoprost, as adjunctive therapy to timolol in patients not responding adequately to timolol alone, reduced IOP an additional 6 to 7 mm Hg. The side-effect profile of travoprost is similar to that for latanoprost, including increased iris pigmentation and eyelash changes.[21–23] Local irritation may be less with travoprost because the current formulation (Travatan Z) is free of the preservative benzalkonium chloride (BAK). Rather, travoprost is preserved in the bottle with SofZia, which is a unique ionic buffer containing borate, sorbitol, propylene glycol, and zinc.

Bimatoprost

Like travoprost, bimatoprost (Lumigan®) once daily achieved lower target IOPs than did timolol bid. Iris pigmentation changed in 1.1% of patients treated with bimatoprost. In a 6-month randomized multicenter study, bimatoprost once a day lowered IOP more effectively than latanoprost once a day. Side effects were similar between treatment groups; however, conjunctiva hyperemia was more common ($P < .001$) in patients treated with bimatoprost. Overall, the side-effect profile of bimatoprost appears to be similar to that for latanoprost and travoprost.[24–26] The local side effects seen with other PGAs also appear to be relatively common with bimatoprost. In addition to treatment of glaucoma and ocular

hypertension, the FDA approved the cosmetic use of bimatoprost solution under the trade name Latisse®. Latisse® solution is applied with an applicator to the base of the upper eyelashes for the treatment of hypotrichosis (inadequate eyelashes). Eyelash lengthening, thickening, and darkening or pigmentation are seen after 8 to 16 weeks of use.[27]

Tafluprost

Tafluprost (Zioptan®) is a preservative-free product approved by FDA for the reduction of elevated IOP and ocular hypertension. Tafluprost daily in the evening is as effective as latanoprost daily in the evening and timolol 0.5% bid and has demonstrated additive efficacy when administered with timolol. Switch studies evaluating tafluprost in patients receiving BAK-containing agents demonstrated some improvement in adverse effects. As a result, tafluprost is an important option for patients with a documented hypersensitivity to BAK or other PGAs. The adverse-effect profile is similar to other PGAs.[28–32]

Xelpros (Latanoprost Ophthalmic Emulsion)

Xelpros is an ophthalmic emulsion containing latanoprost 50 µg/mL (0.005%) with potassium sorbate 0.47% is added as a preservative. Xelpros is the first formulation of latanoprost that does not contain the common preservative BAK. Dosing is once daily at night, and side effects are similar to latanoprost ophthalmic solution.[33]

β-Adrenergic blockers

Ophthalmic β-adrenergic antagonists block the β-adrenergic receptors in the ciliary epithelium of the eye and lower IOP primarily by decreasing aqueous humor production. On average, β-blockers decrease IOP by 20% to 30% depending on the strength used and the frequency of administration.[34–42]

Timolol (Timoptic®)

Timolol, a nonselective β_1- and β_2-adrenergic antagonist, is one of the most commonly prescribed glaucoma medications. Because timolol was the first ocular β-adrenergic blocker marketed, subsequently marketed ophthalmic β-blockers are usually compared with timolol for safety and effectiveness. Most β-blockers are approved for bid therapy. Therapy is usually initiated with a 0.25% solution administered as one drop bid. Concentrations or dosages exceeding one drop of timolol 0.5% bid do not produce further significant decreases in IOP.[43] In many cases, once daily with the nonselective agents is possible. Evidence suggests that β-blockers decrease aqueous production during the day but have much less effect during sleep. Therefore, dosing first thing in the morning is preferred in order to effectively blunt an early-morning pressure rise while minimizing the risk of systemic hypotension during sleep, when aqueous production is diminished. As systemic absorption occurs, a contralateral IOP-lowering effect in the untreated eye can also be observed.[44] In some cases, an escape phenomenon, or tachyphylaxis, can occur with timolol over time.

Timolol has been associated with a modest reduction of resting pulse rate (5–8 beats/minute),[44,45] worsening of heart failure, and adverse pulmonary effects (eg, dyspnea, airway obstruction, pulmonary failure).[46,47] After chronic administration in susceptible individuals, timolol can cause corneal anesthesia.[48,49] Although uveitis has been reported in patients receiving ophthalmic timolol, a cause-and-effect relationship has not been established.[50,51]

Systemic absorption after topical administration does occur, but it may not be significant in the majority of patients. Care should be taken when timolol is used in patients with sinus bradycardia, heart failure (see Chapter 14, Heart Failure), or pulmonary disease. Systemic side effects could be exaggerated in elderly patients secondary to inadvertent overdosing associated with poor administration technique (see Case 54-1, Question 3).

Timoptic XE®

Timoptic XE®, a timolol ophthalmic gel-forming solution, is administered once daily. The ophthalmic vehicle, gellan gum (Gelrite®), is a solution that forms a clear gel in the presence of monovalent or divalent cations.[52] This ion-activated gelation prolongs precorneal residence time and increases ocular bioavailability, allowing timolol to be administered once daily.[52] Timoptic XE® is comparable to timoptic solution in lowering IOP.[53]

Levobunolol (Betagan®)

Levobunolol, a nonselective β-adrenergic antagonist, is approved for either once-daily or bid administration. Levobunolol 0.5% and 1% are comparable to timolol in lowering IOP. The incidence of adverse reactions, including decreases in heart rate, is also comparable to that for timolol.[35,54]

Metipranolol (OptiPranolol®)

Another nonselective β-adrenergic blocking agent, metipranolol 0.1% to 0.6%, is comparable to timolol 0.25% to 0.5% in reducing IOP.[36,37] Like timolol, metipranolol produces corneal anesthesia, which occurs within 1 minute of instillation and returns to baseline after 10 minutes.[48] Metipranolol is associated with a greater incidence of stinging or burning on administration and has been associated with granulomatous anterior uveitis.[55,56] As a result of these side effects, the use of metipranolol is limited.

Carteolol (Ocupress®)

Carteolol, a nonselective β-adrenergic blocking agent with partial β-adrenergic agonist activity, theoretically should minimize the bronchospastic, bradycardic, and hypotensive effects associated with other ocular β-adrenergic blockers.[57] However, no clinical differences were seen when the cardiovascular and pulmonary function effects of carteolol were compared with those of timolol. Carteolol 1% and timolol 0.25% administered bid are equally effective in reducing IOP.[39–41]

Betaxolol (Betoptic®)

In contrast to other β-adrenergic blocking ophthalmic agents, betaxolol is a selective β_1-adrenergic blocker. This cardioselective property may result in less adverse effects on pulmonary function than nonselective β-adrenergic blockers in patients with reactive airway disorders. Betaxolol is slightly less effective than timolol in IOP reduction, and more patients tend to need adjunctive therapy with betaxolol.[42,58–60]

α_2-Adrenergic agonists

Apraclonidine (Iopidine®) and brimonidine (Alphagan®) are selective α_2-adrenergic agonists similar to clonidine. α_2-Adrenergic agonists decrease IOP by constriction of the afferent ciliary process vasculature, leading to decreased aqueous humor production, and also by increasing uveoscleral outflow.[61] Apraclonidine is less lipophilic than clonidine and brimonidine, does not cross the blood–brain barrier as readily, and theoretically has fewer systemic side effects (eg, hypotension, decreased pulse, dry mouth). Brimonidine is more highly selective for α_2-adrenergic receptors than clonidine or apraclonidine and, theoretically, should be associated with fewer ocular side effects.

Brimonidine is an alternative first-line agent in the treatment of POAG. It may also be used as adjunctive therapy in patients not responding to other agents. Apraclonidine 1% is indicated to control or prevent postsurgical elevations in IOP after argon laser trabeculoplasty or iridotomy. The 0.5% apraclonidine solution is indicated for short-term adjunctive therapy in patients on maximally tolerated medical therapy. Long-term IOP control should be monitored closely in patients taking α_2-adrenergic agonists because tachyphylaxis can occur. Common ocular side effects include burning, stinging, blurring, conjunctival follicles, and an allergic-like reaction consisting of hyperemia, pruritus, edema of the lid and conjunctiva, and foreign-body sensation. Topical sensitivity to α_2-adrenergic agonists is seen in ~10% to 20% of patients. These

events may result in discontinuation of treatment in ~12% of patients. Although ocular side effects are less common with brimonidine than with apraclonidine, systemic side effects (eg, dry nose and mouth, mild hypotension, decreased pulse, and lethargy) are more common with brimonidine. α_2-Adrenergic agonists should be used with caution in patients with cardiovascular disease, orthostatic hypotension, depression, and renal or hepatic dysfunction.[61,62] Brimonidine (Alphagan® P) is available with Purite as a preservative, which facilitates drug delivery into the eye, allowing use of a lower drug concentration. The substitution of Purite (in Alphagan® P) for BAK also results in decreased local irritation relative to that seen with the original BAK-containing brimonidine.[62]

The IOP reduction effects (peak and trough) of brimonidine 0.2% bid are 14% to 28%. Although the approved dosing schedule of brimonidine is three times a day (tid), brimonidine 0.2% bid lowers IOP comparably to timolol 0.5% bid, and both are slightly better than betaxolol 0.25% bid.[63,64] The IOP-lowering effect of brimonidine also may be comparable to that of latanoprost; however, conflicting efficacy and tolerability results in clinical studies may be related to differences in study design.[65] The combination of brimonidine and timolol is as equally tolerable and effective as the combination of dorzolamide and timolol.[66] The FDA-approved Combigan® ophthalmic solution combines an α_2-adrenergic agonist (brimonidine tartrate 0.2%) with a β-adrenergic blocker (timolol maleate 0.5%).

Topical carbonic anhydrase inhibitors

Carbonic anhydrase occurs in high concentrations in the ciliary processes and retina of the eye. CAIs lower IOP by decreasing bicarbonate production and, therefore, the flow of bicarbonate, sodium, and water into the posterior chamber of the eye, resulting in a 40% to 60% decrease in aqueous humor secretion.

Although CAIs have been used orally for many years in the treatment of elevated IOPs, they have been replaced by the topical ophthalmic CAIs, dorzolamide (Trusopt®) and brinzolamide (Azopt®), which are safer and better tolerated. Although topical CAIs are

acceptable options in the initial management of elevated IOPs, they are more typically used as secondary or tertiary treatment options owing to their relatively reduced efficacy and increased dosing schedule. They are also effective as adjunctive agents. Brinzolamide 1% tid reduces IOP comparably to that achieved with dorzolamide 2% tid and to betaxolol 0.5% bid, but slightly less than timolol 0.5% bid. The IOP reduction effects (peak and trough) of dorzolamide 2% tid are 16% to 25%. Brinzolamide and dorzolamide are approved for tid dosing; however, bid dosing may be adequate. Dorzolamide provides additional IOP-lowering effects when added to existing β-blocker therapy.[67,68] Typically, CAIs are dosed bid when used as adjunctive therapy and tid when used as monotherapy. An ophthalmic solution of dorzolamide hydrochloride and timolol maleate is marketed as Cosopt®, and a combination of brinzolamide and brimonidine is marketed as Simbrinza™.[69]

The combined use of topical dorzolamide and oral acetazolamide does not result in additive effects and might increase the risk of toxicity. Therefore, the concomitant use of topical and oral CAIs is not advised.[64–66]

The topical CAIs are well tolerated with few systemic side effects. The most common adverse effects reported with dorzolamide are ocular burning, stinging, discomfort and allergic reactions, bitter metallic taste, and superficial punctate keratitis. Corneal epithelial decompensation is possible. Therefore, CAIs should not be used in patients with corneal compromise. Brinzolamide causes less burning and stinging of the eyes than dorzolamide because its pH more closely resembles that of human tears. Dorzolamide and brinzolamide are sulfonamides and may cause the same types of adverse reactions attributable to sulfonamides. These drugs should not be used in patients with renal or hepatic impairment.[70–72]

Nitric oxide donors

In November 2017, the FDA approved latanoprostene bunod ophthalmic solution (Vyzulta®, 0.024%, Bausch & Lomb) for reduction of IOP in patients with open-angle glaucoma or ocular

hypertension. Latanoprostene bunod has a dual mechanism of action. The first is PGA activity (latanoprost), which increases outflow of aqueous humor through the uveoscleral pathway. The second component (butanediol mononitrate) releases NO, which induces cell relaxation in the trabecular meshwork, leading to a widening of intercellular spaces, thereby increasing outflow through the trabecular meshwork. Latanoprostene bunod is dosed once daily. Results from the LUNAR and APOLLO studies have shown that latanoprostene bunod is more effective than timolol with a 32% reduction in IOP from baseline.[73,74] The VOYAGER study compared latanoprostene bunod to latanoprost alone. Latanoprostene bunod was associated with 1.2 mm Hg of additional IOP lowering compared to latanoprost. Safety, tolerability, and side effects of latanoprostene bunod are very similar to those of latanoprost.[75]

Rho-kinase inhibitors

Netarsudil ophthalmic solution (Rhopressa®, 0.02%) is indicated for reduction of IOP in patients with open-angle glaucoma or ocular hypertension. Netarsudil is dosed once daily. Netarsudil has three different mechanisms of action. It increases outflow through the trabecular meshwork, decreases the production of aqueous humor, and decreases episcleral venous pressure. ROCKET-1 and ROCKET-2 studies showed noninferiority of netarsudil to timolol.[76] The studies demonstrated consistent IOP reduction of about 5 mm Hg across a range of baseline IOPs. Efficacy of netarsudil was particularly notable in patients with low baseline IOPs. Common side effects include significant conjunctival hyperemia, small conjunctival hemorrhages at the limbus, and corneal verticillata (whirl-like corneal deposits that are seen in 20% of patients treated with netarsudil).

The combined netarsudil/latanoprost ophthalmic solution (Rocklatan®, 0.02%/0.005%) is indicated for reduction of IOP in patients with open-angle glaucoma or ocular hypertension. This fixed combination of netarsudil/latanoprost is dosed once daily and has a quadruple mechanism of action. The combined netarsudil/latanoprost acts on both the trabecular meshwork and the

uveoscleral outflow pathways to increase aqueous outflow. In addition, it decreases aqueous production and decreases episcleral venous pressure. This combination drug has been shown to reduce IOP by 1 to 3 mm Hg more than either netarsudil or latanoprost monotherapy. Side effects are similar to those of netarsudil and latanoprost.[77]

Pilocarpine

Pilocarpine (Isopto-Carpine®) historically was an initial treatment of choice, but with the introduction and widespread use of newer agents, and unfavorable side effects of pilocarpine (reduced vision, accommodative spasm, and brow ache), pilocarpine has fallen out of favor. Pilocarpine is now typically reserved for refractory cases. Therapy is usually begun using lower concentrations (1%), one drop four times a day (qid). It can also be used in angle-closure attacks. Pilocarpine is a direct-acting cholinergic (parasympathomimetic) that causes contraction of ciliary muscle fibers attached to the trabecular meshwork and scleral spur. This opens the trabecular meshwork to enhance aqueous humor outflow. There may also be a direct effect on the trabecular meshwork. Pilocarpine causes miosis by contraction of the iris sphincter muscle, but the miosis is not related to the decrease in IOP.

Carbachol

Carbachol (Isopto Carbachol®) is reserved as a third-line agent in patients who are unresponsive or intolerant to initial medications. In addition to having direct cholinergic effects, carbachol is more resistant to cholinesterase than pilocarpine. Added benefits include increased release of acetylcholine from parasympathetic nerve terminals and a weak anticholinesterase effect. Carbachol is administered tid.

Anticholinesterase agents

If control of IOP is not achieved with optimal use of other topical monotherapy and combination therapy agents, then anticholinesterase agents may be prescribed as a last topical therapy option. Anticholinesterase agents inhibit the enzyme cholinesterase, thereby increasing the amount of acetylcholine and its naturally occurring cholinergic effects.

Echothiophate iodide

Echothiophate iodide (Phospholine iodide®), an irreversible cholinesterase inhibitor, primarily inactivates pseudocholinesterase and secondarily inhibits true cholinesterase. Echothiophate iodide may be used if maximal doses of other agents and combination therapy are ineffective. Echothiophate iodide has a long duration of action that affords good control of IOP; however, miosis and myopia are significant side effects. Concentrations greater than 0.06% are associated with a significant increase in subjective concerns (eg, brow ache).[78]

COMBINATION THERAPY

In general, drugs with different pharmacologic actions have at least partially additive effects in lowering IOP in the treatment of glaucoma. Drugs with similar pharmacologic actions (ie, from the same pharmacologic class) should not be combined because dose-related adverse effects are more likely and the incremental increase in benefits is likely to be more modest. When considering combination IOP-lowering drugs, it is best to trial at least one of the components first. Combination therapy is rarely initiated first. Monotherapy is typically the first-line treatment, then addition of a second drug via a combination product can be trialed if the initial single drug failed to meet target pressure.[79]

Timolol and other β-adrenergic blocking drugs have additive IOP-lowering effects when used in combination with miotic agents, PGAs, α_2-agonists, and CAIs. For example, the IOP-lowering effect is greater when timolol is used in combination with pilocarpine, dorzolamide, brimonidine, and travoprost. Likewise, for example,

latanoprost has additive effects when administered with timolol, dorzolamide, and α_2-adrenergic agonists.[16–20,80–85] The trend toward the development of fixed combination products offers many advantages in the treatment of POAG. These advantages include improved adherence because of a reduction in the number of dosages and bottles, eliminating the need to instill two separate drugs 5 to 10 minutes apart to prevent a washout effect from the second medication, improving safety and tolerability by limiting the exposure to the BAK preservative, and a cost savings for the patient by potentially eliminating a copay for one of the medications. There are two β-adrenergic blocker combination products currently on the market, timolol/dorzolamide (Cosopt®) and brimonidine/timolol (Combigan®). The IOP-lowering effects of timolol/dorzolamide (Cosopt®) are comparable to or greater than those of latanoprost monotherapy.[71] Brinzolamide and brimonidine are combined and available as Simbrinza™.[69]

Predisposing Factors

CASE 54-1

Question 1: L.S., a 65-year-old African American male with brown eyes, presented for routine eye examination. Visual acuity with correction was 20/20 in the right eye and 20/25 in the left eye. Pupils were normal in both eyes. IOP via Goldmann Applanation tonometry was 26 mm Hg in the right eye and 24 mm Hg in the left eye. Anterior chamber angles were open in both eyes on gonioscopic examination. Dilated fundus examination with ophthalmoscopy revealed large cupping of the optic discs in both eyes, with thinning of the neuroretinal rim tissue, and corresponding nerve fiber bundle defects. There were no signs of cataract formation. Visual field examination revealed superior and inferior arcuate bundle defects consistent with glaucoma. L.S. related a positive family history of glaucoma and presently is being treated for systemic hypertension, chronic heart failure (CHF), chronic obstructive pulmonary disease, and asthma. His medications include the following:

Amitriptyline, 75 mg at bedtime
Chlorpheniramine, 4 mg every 6 hours as needed (PRN)
Lisinopril, 10 mg once daily
Furosemide, 40 mg bid

Nitroglycerin, 0.3 mg sublingual PRN
Fluticasone/salmeterol 250/50 µg dry powder inhaler, one inhalation bid
Albuterol 90 µg metered-dose inhaler, 1 to 2 puffs qid PRN
Tiotropium bromide inhaler, 18 µg inhaled once daily

Findings on examination indicate that L.S. has POAG. What other factors may predispose L.S. to an increased IOP?

POAG is thought to have a genetic component, and L.S. has a positive family history. The disease is more prevalent and aggressive in African Americans.[1] In addition, he is taking several medications that have been associated with increases in IOP.

ANTICHOLINERGIC DRUGS

Most reports dealing with drug-induced increases in IOP center around precipitation of angle-closure glaucoma by ophthalmic mydriatic or cycloplegic agents (anticholinergics). In patients with open-angle glaucoma, topical anticholinergics can significantly increase resistance to aqueous humor outflow and elevate IOP, while the anterior chamber remains grossly open.[6] As part of any routine ophthalmic examination, the pupils are dilated with a mydriatic or cycloplegic agent (unless otherwise contraindicated). The IOP is always measured before this procedure, so the use of these agents would not have influenced the IOP readings for L.S.

If systemic anticholinergic agents are administered in doses sufficient to cause pupillary dilation, the risk of precipitating angle-closure increases. However, it is unlikely that these agents will aggravate open-angle glaucoma unless the amount reaching the eye is sufficient to cause cycloplegia.[6] Although literature documentation of POAG exacerbation by these agents is scarce, medications with anticholinergic side effects (eg, antihistamines, benzodiazepines, disopyramide, phenothiazines, tricyclic antidepressants, tiotropium) should be considered. L.S. is receiving chlorpheniramine PRN, amitriptyline at bedtime, and tiotropium bromide once daily, but his pupil examination is normal with no evidence of mydriasis or cycloplegia. Therefore, it is highly unlikely that these medications contributed to his increased IOP.

ADRENERGIC DRUGS

Adrenergic agents, such as central nervous system stimulants, vasoconstrictors, appetite suppressants, and bronchodilators, may produce minimal pupillary dilation. These have no proven adverse influences on IOP in patients with either normal eyes or eyes with open-angle glaucoma. Consequently, the use of salmeterol and albuterol in L.S. is also an unlikely source of the increased IOP.

OTHER DRUGS

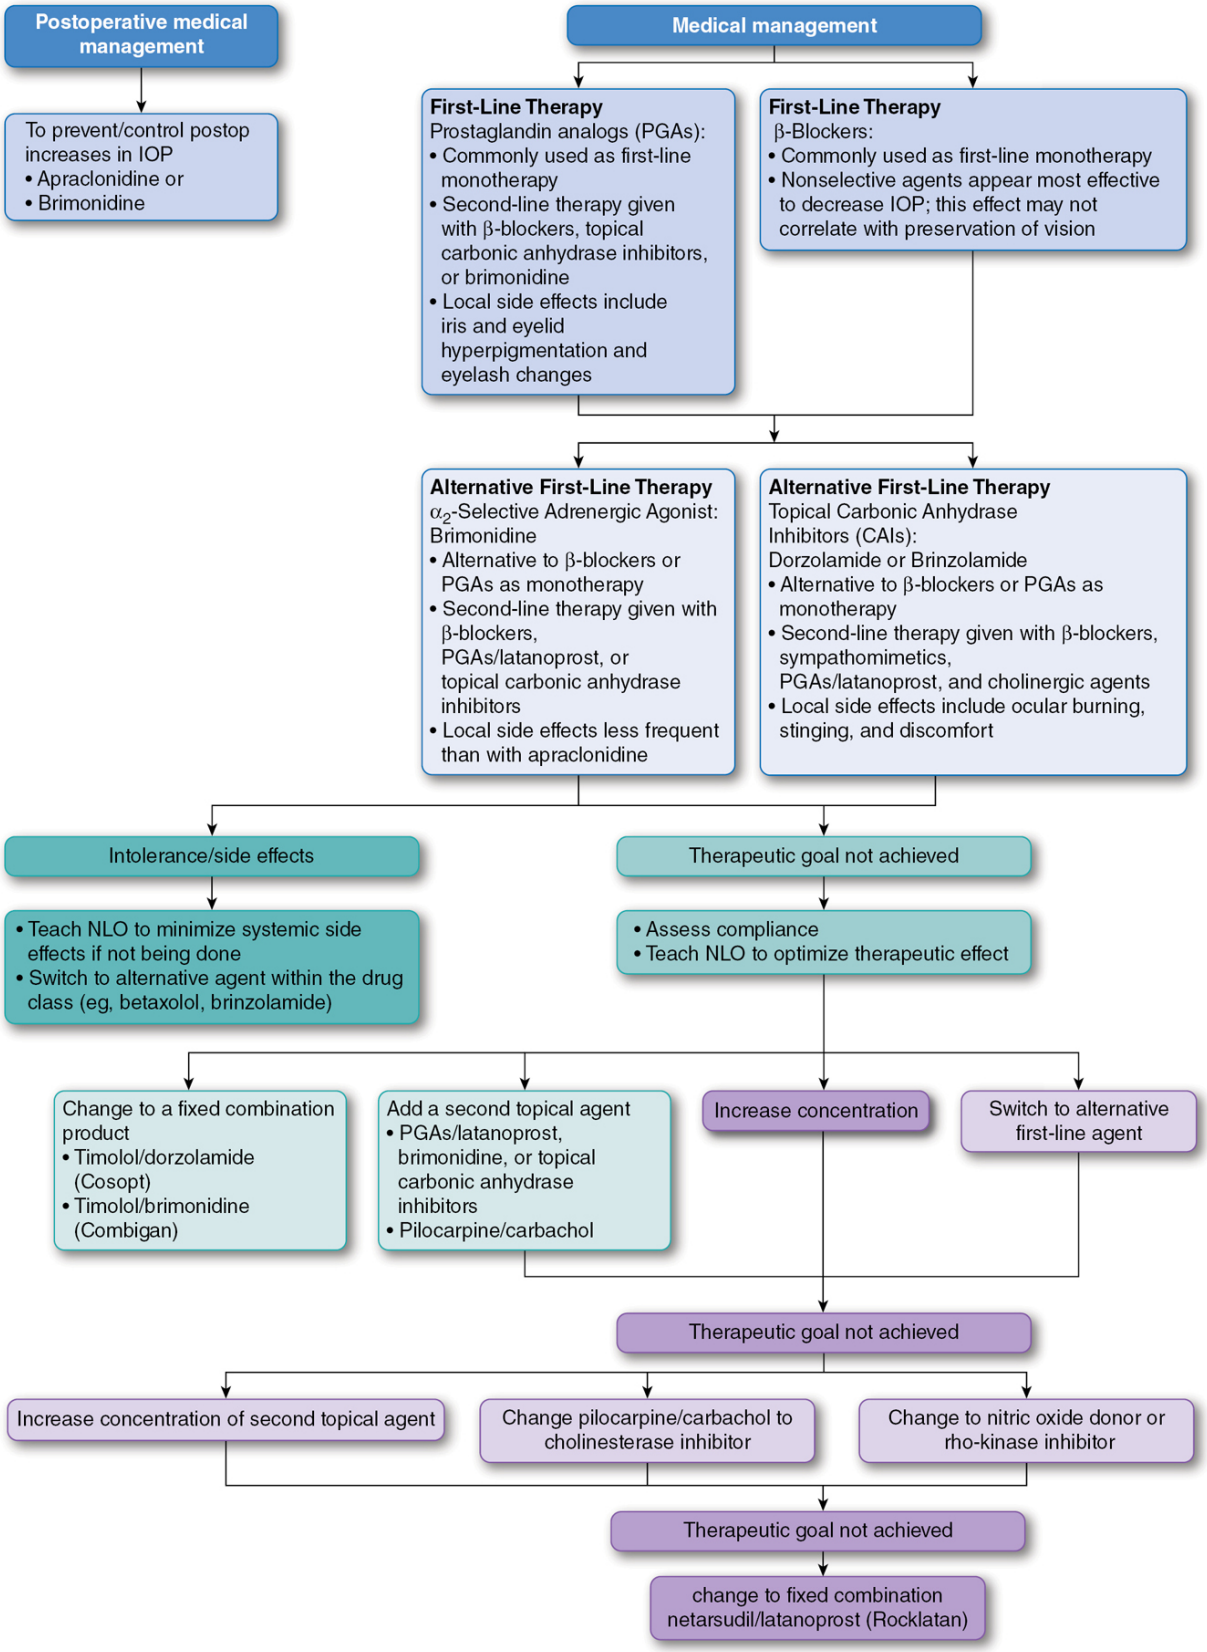
Conclusive evidence for the production of angle-closure glaucoma by vasodilators is lacking, although slight increases in IOP have been reported. The use of nitroglycerin PRN for L.S. is not a cause for concern. There have been isolated reports of other medications causing mydriasis in patients with glaucoma, including muscle relaxants (carisoprodol), monoamine oxidase inhibitors, fenfluramine, ganglionic blocking agents, salicylates, and oral contraceptives. Succinylcholine, ketamine, and caffeine have been associated with increases in IOP. Corticosteroid-induced IOP elevation has been shown in systemic, topical, and inhaled corticosteroid use. IOP elevation occurs more frequently with topical administration of corticosteroids (drops or ointment applied directly to the eye or over the skin of the eyelids) than with systemic or inhaled administration. However, studies have shown a strong association between inhaled corticosteroid and the presence of ocular hypertension in patients with family history of glaucoma. The risk increases with higher dose and more puffs. The use of fluticasone/salmeterol inhaler bid could pose a risk for increased IOP in L.S. Corticosteroid-induced IOP elevation is addressed further in Case 54-8, Question 2.

If L.S. requires administration of any other medications associated with increases in IOP, the risk of potential adverse effects can be minimized by routine follow-up, with modification of treatment PRN.

Initial Therapy

Case 54-1, Question 2: It is determined that L.S. has POAG and requires initiation of treatment with a goal of 30% reduction in IOP (18 mm Hg in the right eye, 17 mm Hg in the left eye) in order to halt the progression of glaucoma. What is the best initial therapeutic treatment for L.S.?

PGAs (or in some cases topical β-blockers) are the initial agents of choice in the treatment of POAG (**Fig. 54-2**). Their efficacy is well documented in numerous studies, and side effects are well characterized. Brimonidine (Alphagan®) and topical CAIs are alternative first-line agents. **Table 54-1** lists the common topical agents used in the treatment of POAG.



Postoperative medical management
To prevent/control postop increases in IOP
• Apraclonidine or
• Brimonidine
Medical management
First-Line Therapy
Prostaglandin analogs (PGAs):
• Commonly used as first-line monotherapy
• Second-line therapy given with β-blockers, topical carbonic anhydrase inhibitors, or brimonidine
• Local side effects include iris and eyelid hyperpigmentation and eyelash changes
First-Line Therapy
β-Blockers:
• Commonly used as first-line monotherapy
• Nonselective agents appear most effective to decrease IOP; this effect may not correlate with preservation of vision
Alternative First-Line Therapy
α2-Selective Adrenergic Agonist: Brimonidine
• Alternative to β-blockers or PGAs as monotherapy
• Second-line therapy given with β-blockers, PGAs/latanoprost, or topical carbonic anhydrase inhibitors
• Local side effects less frequent than with apraclonidine
Alternative First-Line Therapy
Topical Carbonic Anhydrase Inhibitors (CAIs):
Dorzolamide or Brinzolamide
• Alternative to β-blockers or PGAs as monotherapy
• Second-line therapy given with β-blockers, sympathomimetics, PGAs/latanoprost, and cholinergic agents
• Local side effects include ocular burning, stinging, and discomfort
Intolerance/side effects
• Teach NLO to minimize systemic side effects if not being done
• Switch to alternative agent within the drug class (eg, betaxolol, brinzolamide)
Therapeutic goal not achieved
• Assess compliance
• Teach NLO to optimize therapeutic effect
Change to a fixed combination product
• Timolol/dorzolamide (Cosopt)
• Timolol/brimonidine (Combigan)
Add a second topical agent
• PGAs/latanoprost, brimonidine, or topical carbonic anhydrase inhibitors
• Pilocarpine/carbachol
Increase concentration
Switch to alternative first-line agent
Therapeutic goal not achieved
Increase concentration of second topical agent
Change pilocarpine/carbachol to cholinesterase inhibitor
Change to nitric oxide donor or rho-kinase inhibitor
Therapeutic goal not achieved
change to fixed combination netarsudil/latanoprost (Rocklatan)

Figure 54-2 Medical management of glaucoma. IOP, intraocular pressure; NLO, nasolacrimal occlusion.

Table 54-1
Common Topical Agents Used in the Treatment of Open-Angle Glaucoma

Generic	Mechanism	Strength	Usual Dosage	Comments
Prostaglandin Analogs				
Bimatoprost (Lumigan®)	Prostamide	0.01%, 0.03%	One drop once a day at bedtime	Bid dosing may be less effective than qhs dosing. May cause increased pigmentation of the iris and eyelid. Systemic side effects are rare but include colds and upper respiratory tract infections and headache. May be more effective than timolol and latanoprost
Latanoprost (Xalatan®)	Prostaglandin $F_{2\alpha}$ agonist	0.005%	One drop once a day at bedtime	Bid dosing may be less effective than once a day at bedtime dosing. May cause increased pigmentation of the iris and eyelid. Systemic side effects are rare but may cause muscle, joint, back pain, headaches, migraines, and skin rash. Effective monotherapy or adjunctive therapy. Store unopened bottles in refrigerator. Opened bottles may be stored at room temperature up to 6 weeks.
Latanoprost ophthalmic emulsion (Xelpros™)	Prostaglandin $F_{2\alpha}$ agonist	0.005%	One drop once a day at bedtime	Bid dosing may be less effective than once a day at bedtime dosing. May cause increased pigmentation of the iris and eyelid. Systemic side effects are rare but may cause muscle, joint, back pain, headaches, migraines, and skin rash. Effective monotherapy or adjunctive therapy. Store unopened bottles in refrigerator. Opened bottles may be stored at room temperature up to 6 weeks BAK-free formulation of latanoprost
Tafluprost (Zioptan®)	Prostaglandin $F_{2\alpha}$ agonist	0.0015% preservative-free dropperette	One drop once a day at bedtime	Bid dosing may be less effective than qhs dosing. May cause increased pigmentation of the iris and eyelid. Systemic side effects are rare but include common cold, cough, headache, and urinary tract infections. Store unopened foiled pouches in refrigerator. Single-use container may be stored in the opened foil pouch for 28 days at room temperature.
Travoprost (Travatan Z®)	Prostaglandin $F_{2\alpha}$ agonist	0.004%	One drop once a day at bedtime	Bid dosing may be less effective than once a day at bedtime dosing. May cause increased pigmentation of the iris and eyelid. Systemic side effects are rare, but may include colds and upper respiratory tract infections. Effective monotherapy or adjunctive therapy with timolol. May be more effective than timolol and latanoprost and more effective in African Americans. Does not contain benzalkonium chloride as a preservative. Contains the preservative SofZia that may be better tolerated.
β-*Adrenergic Blockers*				
Betaxolol (Betoptic [solution], Betoptic S® [suspension])	Sympatholytic	0.25% (suspension) 0.5% (solution)	One drop bid One drop bid	Shake suspension well before use. Effective with few associated ocular side effects. Bid dosage enhances compliance. Considered β-blocker of choice in patients with preexisting HF or pulmonary disease because of β_1-adrenergic specificity. Patient response may be less than that seen with timolol.
Carteolol (Ocupress®)	Sympatholytic	1%	One drop bid	Effective with few associated side effects. Bid dosage enhances compliance. Use with caution in patients with preexisting HF or pulmonary disease.

Levobunolol (Betagan®)	Sympatholytic	0.25%, 0.5%	One drop daily or bid	Effective with few associated ocular side effects. Daily and bid dosage enhances compliance. Use with caution in patients with preexisting HF or pulmonary disease.
Metipranolol (OptiPranolol®)	Sympatholytic	0.3%	One drop bid	Effective with few associated side effects. Bid dosage enhances compliance. Use with caution in patients with preexisting HF or pulmonary disease.
Timolol (Timoptic®) (Betimol®) (Istalol®)	Sympatholytic	0.25%, 0.5% 0.5% (Istalol®) 0.25%, 0.5% preservative-free (Timoptic Ocudose)	One drop bid One drop daily in the morning (Istalol®)	Effective with few associated ocular side effects. Daily and bid dosage enhances compliance. Use with caution in patients with preexisting HF or pulmonary disease. Proven long-term effectiveness, with well-defined side-effect profile
Timolol Gel-Forming Solution (Timoptic XE, Timolol GFS)	Sympatholytic	0.25%, 0.5%	One drop daily	Once-daily timolol formulation. The ophthalmic vehicle, gellan gum (Gelrite), prolongs precorneal residence time and ↑ ocular bioavailability, allowing once-daily administration.
α_2-Selective Adrenergic Agonists				
Apraclonidine (Iopidine)	Sympathomimetic	0.5%, 1%	One drop preoperatively and postoperatively or one drop bid to tid	May be used preoperatively and postoperatively for the prevention of ↑ IOP after anterior-segment laser procedures. Use of NLO minimizes systemic side effects and allows for bid dosing. Does not penetrate the blood–brain barrier, therefore negligible systemic hypotension. Local adverse effects fairly common. Tachyphylaxis may be observed.
Brimonidine (Alphagan®)	Sympathomimetic	0.15%, 0.2%	One drop bid to tid	Effective long-term monotherapy or adjunctive therapy. Use of NLO minimizes systemic side effects and allows for bid dosing. Penetrates the blood–brain barrier, therefore may cause mild systemic hypotension and lethargy. Local adverse effects less common than with apraclonidine
Brimonidine (Alphagan® P)	Sympathomimetic	0.1%, 0.15%	One drop bid to tid	Contains Purite preservative. Purite preservative and lower concentrations may improve tolerability.
Topical Carbonic Anhydrase Inhibitors				
Brinzolamide (Azopt®)	Decreased aqueous humor production	1%	One drop tid	Shake suspension well before use. Effective long-term monotherapy or adjunctive therapy. Well tolerated with few systemic side effects. Less burning and stinging compared with dorzolamide
Dorzolamide (Trusopt®)	Decreased aqueous humor production	2%	One drop tid	Effective long-term monotherapy or adjunctive therapy. Well tolerated with few systemic side effects
Nitric Oxide Donors				
Latanoprostene bunod (Vyzulta®)	Nitric oxide–donating prostaglandin $F_{2\alpha}$ analog	0.024%	One drop once a day at bedtime	Bid dosing may be less effective than once a day at bedtime dosing. May cause increased pigmentation of the iris and eyelid. Systemic side effects are rare but may cause muscle, joint, back pain, headaches, migraines, and skin rash. Effective monotherapy or adjunctive therapy. Store unopened bottles in refrigerator. Opened bottles may be stored at room temperature up to 6 weeks.

Rho-Kinase Inhibitor				
Netarsudil (Rhopressa®)	ROCK inhibitor plus norepinephrine transporter: increase trabecular meshwork outflow, lower episcleral venous pressure, decrease aqueous production	0.02%	One drop once a day at bedtime	Significant conjunctival hyperemia, small conjunctival hemorrhages, and corneal deposits. Particularly effective in patients with low baseline IOPs.
Miotics				
Pilocarpine (Isopto® Carpine)	Parasympathomimetic	1%, 2%, 4%	One to two drops tid or qid	Long-term proven effectiveness. Little rationale for administration more frequently than every 4 hours. Side effects of miosis with decreased vision and brow ache are common sources of patient problems.
Carbachol (Isopto® Carbachol)	Parasympathomimetic	1.5%, 3%	One to two drops tid or qid	Used in patients allergic to or intolerant of other miotics. May be used as frequently as every 4 hours. Corneal penetration is enhanced by benzalkonium chloride in commercial preparations. Side effects are similar to those of pilocarpine.
Echothiophate iodide (Phospholine iodide®)	Anticholinesterase	0.125%	One drop bid	Long duration, although usually dosed bid, which enhances compliance. Available as powder plus diluent; after reconstitution, stable 30 days at room temperature, 6 months refrigerated. Side effects similar to those of pilocarpine. Increased cataract formation has been associated with its use.
Combination Products				
Brimonidine tartrate 0.2%/timolol 0.5% (Combigan)	Sympathomimetic/ sympatholytic	0.2%/0.5%	One drop bid	Combination products may improve adherence. Eliminates the 5- to 10-minute wait between instillation of drops
Brinzolamide 1%/brimonidine 0.2% (Simbrinza™)	Decreased aqueous humor production/sympathomimetic	1%/0.2%	One drop tid	Shake suspension well before use. Combination products may improve adherence. Eliminates the 5- to 10-minute wait between instillation of drops
Dorzolamide 2%/timolol 0.5% (Cosopt®)	Decreased aqueous humor production/ sympatholytic	2%/0.5% 2%/0.5% preservative free (Cosopt® PF)	One drop bid	Combination products may improve adherence. Eliminates the 5- to 10-minute wait between instillation of drops
Netarsudil/latanoprost (Rocklatan®)	Netarsudil plus latanoprost: increase trabecular meshwork and uveoscleral outflow, lower episcleral venous pressure, decrease aqueous production	0.02%/0.005%	One drop once a day at bedtime	Significant conjunctival hyperemia, small conjunctival hemorrhages, and corneal deposits. Bid dosing may be less effective than once a day at bedtime dosing. May cause increased pigmentation of the iris and eyelid. Systemic side effects are rare but may cause muscle, joint, back pain, headaches, migraines, and skin rash. Particularly effective in patients with low baseline IOPs.

Bid, twice daily; GFS, gel-forming solution; HF, heart failure; IOP, intraocular pressure; NLO, nasolacrimal occlusion; qhs, every day at bedtime; qid, four times a day; tid, three times a day.

Timolol or other nonselective β-adrenergic blockers should not be initiated for L.S. because of his history of asthma and chronic

obstructive pulmonary disease (the indications and use of β-blockers for patients with heart failure are described in Chapter 14, Heart Failure). Betaxolol, a β_1-adrenergic blocker, is better tolerated than the nonselective β-adrenergic blocker, timolol, in patients with reactive airway disease and could be considered in cases in which topical β-blocker therapy is the only viable option.[40,58,59,86] L.S. does not have any contraindications for PGA use. Therefore, latanoprost 0.005% every day at bedtime (qhs) would be the ideal initial treatment of L.S.'s glaucoma because of its once-a-day dosing and superior efficacy. Travoprost is another PGA option that has been shown to be particularly effective in African Americans.[21] In this case, latanoprost was chosen because it was available as a cost-effective generic formulation.

Betaxolol 0.25% suspension bid could be an acceptable alternative to latanoprost if L.S. had contraindications for use of PGAs. Betaxolol is a cardioselective β_1-adrenergic blocker; nevertheless, adverse pulmonary and cardiac side effects can still occur with betaxolol. L.S. would need to be followed closely for these adverse effects. Although ocular burning and stinging have been associated more frequently with betaxolol and metipranolol than with other topical β-blockers, the 0.25% suspension is better tolerated than the 0.5% solution and is as effective.[58] Brimonidine and topical CAIs are other alternatives to latanoprost as initial therapy. Although brimonidine and topical CAIs may not exacerbate his asthma or CHF, they can cause localized side effects and brimonidine can cause systemic hypotension and lethargy.

Patient Education

Case 54-1, Question 3: Latanoprost 0.005%, one drop in both eyes qhs, is ordered for L.S. How should L.S. be instructed regarding the proper use of his latanoprost and expected therapeutic side effects?

L.S. should be instructed to hold the inverted latanoprost bottle between his thumb and middle finger and to rest that hand on his

forehead to minimize the risk of inadvertent eye injury caused by sudden unexpected movement of the hand. The index finger is left free to depress the bottom of the container, releasing one drop for the dose. With a little practice, this technique is easy to master. The lower eyelid should be drawn downward with the index finger of the opposite hand to form a pouch. The patient should look up and administer the drug into the pouch of the eye.

Patients must be encouraged to continue regular use of their medications for effective treatment of glaucoma. Chronic glaucoma is a silent disease and often not associated with symptoms; therefore, the continuation of therapy should be encouraged continuously in patients, especially when side effects to drug therapy can be encountered. Latanoprost is best administered every 24 hours in the evenings because this schedule of administration is consistent with its duration of action (see Table 54-1).

L.S. should be informed of the PGA-induced potential for hyperpigmentation of the iris, which may be permanent. He also needs to be educated on the possibility of periorbital fat atrophy, eyelid skin darkening, and increased thickness, length, and pigmentation of his eyelashes, which all may or may not be reversible. These side effects might not be as cosmetically concerning to L.S., because he has brown eyes and will be instilling latanoprost eye drops into both eyes so the effects would be symmetrical. Systemic side effects (eg, muscle, joint, and back pain; headaches; migraines; skin rash) are rare with latanoprost, but L.S. should be instructed to report any of these effects to his primary care provider.

NASOLACRIMAL OCCLUSION

Case 54-1, Question 4: How much would occlusion of the nasolacrimal ducts (punctal occlusion) by L.S. influence systemic absorption or alter the therapeutic effects of latanoprost?

Nasolacrimal, or punctal, occlusion is a technique that can decrease the amount of drug absorbed systemically.[87] Occlusion of the puncta (through the application of slight pressure with the finger to the inner corner of the eye closest to the nose for 3 to 5 minutes during and after drug instillation) can minimize systemic absorption of ophthalmic medications, decrease the incidence of side effects, and improve medication effectiveness.[87–89] When a single drop of ophthalmic timolol 0.5% was instilled into the eyes of patients at various times before cataract surgery and the nasolacrimal duct was occluded for 5 minutes, drug levels in the aqueous humor were significantly greater in patients who had their nasolacrimal ducts occluded than those who did not.[88] Nasolacrimal occlusion is effective and can maximize drug benefits and decrease systemic absorption and side effects.[81]

Alternative Therapy

Case 54-1, Question 5: Two weeks after initiation of therapy, L.S. returns to clinic for a follow-up evaluation. His IOP measures 22 mm Hg in the right eye and 21 mm Hg in the left eye. Although the latanoprost did lower the IOP in each eye, it did not reach the treatment goal (ie, target IOP). He denies nonadherence and has no intolerable side effects. How should therapy be altered? What alternative dosage forms or drugs can be used?

L.S. should be evaluated to determine whether he has been using proper technique when instilling the drops and performing nasolacrimal occlusion. If not, L.S. should be again instructed on proper technique and nasolacrimal occlusion and the importance of this technique in achieving the maximal therapeutic effect of her therapy (see Case 54-1, Question 4).

After the initiation of therapy, patients should be seen for a follow-up evaluation within about 2 weeks. If L.S. has been adherent to therapy and has been occluding his nasolacrimal ducts, a new course of action is needed because his IOP still is elevated. When the goal of therapy has not been achieved, the drug concentration of

the ophthalmic formulation can be increased, adjunctive therapy (eg, betaxolol, brimonidine, or a topical CAI) can be initiated, or an alternative first-line agent can be selected. Patients who are experiencing unstable reductions of IOP should be followed up within 3 months.[7] Stable patients are usually evaluated every 6 months.[7]

Adverse Effects

Case 54-1, Question 6: After the follow-up evaluation, dorzolamide 2% solution, one drop both eyes bid, is added to L.S.'s latanoprost therapy. This option was selected in order to avoid potential local and systemic side effects of brimonidine, as well as potential systemic side effects of betaxolol. Two weeks later, L.S. returns for a follow-up evaluation for bilateral stinging and foreign-body sensation. His IOP measures 22 mm Hg in the right eye and 21 mm Hg in the left eye. What are the possible causes of his side effects and poor response to therapy?

The exposure of dorzolamide to the outside environment may result in the aggregation of dry white granules on the tip of the dorzolamide bottle. These granules can drop into a patient's eyes when instilling the medication, leading to local side effects, such as stinging and foreign-body sensation. Such foreign bodies may cause enough discomfort to induce nonadherence, resulting in a poor response to therapy. These granules may be rinsed off the tip with sterile water. L.S. should be questioned about the presence of dry white granules on the tip of his dorzolamide bottle.[90]

These problems may also be a side effect from the medications, regardless of the granule presence. Ocular burning, stinging, and discomfort were reported in one-third of patients in dorzolamide clinical trials. L.S.'s administration technique should also be assessed to determine whether he is administering the two drugs at least 5 to 10 minutes apart so that the first drug is not washed away by the second drug. This should be a consideration when assessing his response to therapy.[43]

Case 54-1, Question 7: After further discussions with L.S., it is determined that he has not been adherent to his dorzolamide therapy because of intolerable side effects. The dorzolamide is discontinued and replaced with brimonidine (Alphagan® P) 0.1% one drop both eyes bid. What are the benefits of Alphagan® P? What patient education information should be provided to L.S. about side effects of brimonidine?

Brimonidine is a reasonable adjunctive therapy in patients who are not responding to or are having intolerable side effects from other medications. Alphagan® P is an ideal formulation for L.S. because it contains Purite preservative and is available in a lower concentration, which may decrease side effects and improve tolerability. Nevertheless, L.S. still needs to be informed about the potential for localized ocular sensitivity reactions (burning, stinging, blurring, conjunctival follicles, and an allergic-like reaction), systemic hypotension, and lethargy.

ANGLE-CLOSURE GLAUCOMA

Treatment

CASE 54-2

Question 1: D.H., a 72-year-old male, presents to the emergency department with an intensely red right eye, a "steamy" appearing cornea, haloes around lights, and extreme pain. A diagnosis of acute angle-closure glaucoma is made.
How should D.H. be managed?

D.H. should be seen immediately by an ophthalmologist because acute angle-closure glaucoma is a medical emergency. Medical treatment usually consists of pilocarpine 2% to 4%, one drop every 5 minutes for four to six administrations. It is recommended that the puncta be covered during administration to decrease the possibility of systemic absorption. Stronger miotic agents are contraindicated

because they may potentiate angle closure. Topical timolol also has been used in acute angle-closure glaucoma, commonly in combination with pilocarpine. However, drugs that decrease aqueous humor production may be ineffective in this situation because they have a decreased ability to reduce aqueous production if the ciliary body is ischemic.[7]

HYPEROSMOTIC AGENTS

Hyperosmotic agents (**Table 54-2**) act by creating an osmotic gradient between the plasma and ocular fluids.[91] Agents that are confined to the extracellular fluid space (eg, mannitol) provide a greater effect on blood osmolality at the same dosage than do agents distributed in total body water.[91] Intravenously administered drugs provide a faster, somewhat greater effect than oral agents. Palatability may be a problem with oral agents and can be improved by serving these agents over crushed ice or with lemon juice or cola flavoring.

Table 54-2
Hyperosmotic Agents

Generic	Mode of Administration	Strength	Onset	Peak	Duration	Dose (g/kg)	Ocular Penetration	Distribution
Mannitol	IV	5%, 10%, 15%, 20%	30–60 minutes	1 hour	6–8 hours	1–2	Very poor	E
Glycerin	PO	50%	10–30 minutes	30 minutes	4–5 hours	1–1.5	Poor	E
Isosorbide	PO	45%	10–30 minutes	1 hour	5 hours	1.5–2	Good	TBW

E, extracellular water; IV, intravenous; PO, orally; TBW, total body water.

Orally, 50% glycerin is the usual drug of choice and is administered in dosages of 1 to 1.5 g/kg.[92] Isosorbide is an alternative, especially in patients with diabetes because it is not metabolized to provide calories.[93] Parenterally, mannitol is the drug of choice. It is administered in doses of 1 to 2 g/kg, is not metabolized to provide calories, and may be used in patients with renal failure.[94,95]

Primary side effects of hyperosmotic agents include headache, nausea, vomiting, diuresis, and dehydration. It is important that the

patient not be allowed to drink because this will counteract the osmotic effects of these agents.

Precipitation of pulmonary edema and CHF has been reported with hyperosmotic agents, and an allergic reaction has been reported with mannitol.[96]

Acetazolamide (Diamox) 500 mg intravenously may be administered in addition to hyperosmotic agents.

OCULAR SIDE EFFECTS OF DRUGS

CASE 54-3

QUESTION 1: B.C., a 64-year-old male, has a history of hypertension managed with hydrochlorothiazide 25 mg/day. He takes amiodarone 800 mg/day for cardiac arrhythmia and chlorpheniramine 12 mg bid PRN for allergies. Four weeks ago, risperidone 1 mg bid was added to his medication regimen. He also takes sildenafil 100 mg an average of twice weekly. He reports occasional blurred vision.

Could these symptoms be related to his medications?

All the drugs that B.C. is taking have been associated with ocular side effects. Thiazide diuretics have been associated with acute myopia that may last from 24 to 48 hours.[97,98] However, hydrochlorothiazide is an unlikely cause of B.C.'s blurred vision considering its recent onset.

Amiodarone can cause keratopathy, but it is asymptomatic.[99,100] A high percentage of patients who receive this drug exhibit microdeposits within the corneal epithelium that resembles the verticillata keratopathy induced by chloroquine.[97] These corneal deposits are bilateral, dose and duration related, reversible, and unassociated with visual symptoms.

Risperidone has been associated with disturbances of accommodation and blurred vision.[101]

B.C. may be in the ~1% of the population who experiences blurred vision with chlorpheniramine. This effect has been seen in patients

receiving 12 to 14 mg/day.[97] If an antihistamine is indicated, an agent such as cetirizine would be less likely to cause such an effect. Sildenafil has been associated with change in color and light perception as well as blurred vision.[102] These effects generally subside within 4 hours of the dose.

Table 54-3[97–127] outlines some of the more common ocular side effects associated with systemic medications. Each case should be evaluated individually, and alternative therapy considered in intolerant patients.

Table 54-3
Ocular Side Effects of Systemic Medications

Drug Class	Effect(s)	Clinical Remarks
Analgesics		
Narcotics, including pentazocine	Miosis	Miosis often with morphine in normal doses: slight with other agents; effect secondary to CNS action on the pupilloconstrictor center[97]
	Tearing Irregular pupils Paresis of accommodation Diplopia	Effects associated with narcotic withdrawal[97]
Antiarrhythmics		
Amiodarone	Keratopathy	Dose and duration related; resembles chloroquine keratopathy. Corneal deposits are bilateral, reversible, and unassociated with visual symptoms. Patients taking 100–200 mg/day have only minimal deposits. Deposits occur in almost 100% of patients receiving 400 mg/day[99,100]

Drug Class	Effect(s)	Clinical Remarks
	Cataracts	Previously reported as insignificant, anterior subcapsular lens opacities have been associated with amiodarone therapy. Rarely, such opacities may progress, increasing in density and in the diffuse distribution of the deposits, ultimately covering an area somewhat larger than the undilated pupil's aperture. The mechanism for this effect is unclear, but like chlorpromazine, amiodarone is a photosensitizing agent. Given that the lens changes are limited largely to the pupillary aperture, light exposure may result in the lens changes[97–100]
	Optic neuropathy	Approximately 2% of patients experience optic neuropathy[102]
Anticholinergics		
Atropine Dicyclomine Glycopyrrolate Propantheline Scopolamine Trihexyphenidyl	Mydriasis Cycloplegia with ↓ accommodation Photophobia	Systemic and transdermal anticholinergic agents may cause mydriasis and, less frequently, cycloplegia. Mydriasis may precipitate angle-closure glaucoma. Photophobia is related to mydriasis. Accommodation for near objects[97,103]
Anticonvulsants		
Carbamazepine	Diplopia Blurred vision	Ocular adverse reactions when dosage >1–2 g/day; disappear when dosage is reduced[97]
Phenytoin	Nystagmus cataracts	Nystagmus in patients with high blood levels (>20 μg/mL); rarely occurs with other hydantoins. Cataracts may occur rarely with prolonged therapy[97,104]

Drug Class	Effect(s)	Clinical Remarks
Topiramate	Acute myopia, secondary angle-closure glaucoma	Topiramate has been associated with angle-closure glaucoma. Symptoms including ocular pain, headache, nausea, vomiting, hyperemia, visual field defects, and blindness have been reported. This process is usually bilateral, but if symptoms are recognized and the drug is stopped in a timely manner, adverse outcomes may be minimized[102]
Trimethadione	Visual glares	A prolonged glare or dazzle occurs when eyes are exposed to light. The glare is reversible, occurs at the retinal level, and is more common in adolescents and adults; rarely in young children[97]
Vigabatrin	Visual field abnormalities	Visual field abnormalities including bilateral, symmetrical, and irreversible peripheral constriction occur in up to 30% of patients. Most patients are asymptomatic, and <0.1% of patients are clinically affected[102]
Antidepressants		
Tricyclic antidepressants (TCAs)		Mydriasis is the most common ocular side effect of TCAs. Cycloplegia is rare. Reports of precipitation of angle-closure glaucoma.[97]
Anti-Infectives		
Amantadine	Corneal lesions	Diffuse, white punctate subepithelial corneal opacities have been reported, occasionally associated with superficial punctate keratitis. Onset has been 1–2 weeks after initiation of therapy with dosages of 200–400 mg/day. Resolves with drug discontinuation[105]

Drug Class	Effect(s)	Clinical Remarks
Chloroquine	Corneal deposits	Some patients using ordinary doses may develop corneal deposits in a few months. The deposits are visible with use of a biomicroscope and appear as white yellow in color, but are of no consequence[97]
	Retinopathy (macular degeneration)	Serious retinopathy when total dose >100 g. Usually develops after 1–3 years; can occur in 6 months. Visual loss may be peripheral, with progression to central vision loss and disturbance of color vision. Rarely, effects such as blurred vision are seen earlier when larger doses (500–700 mg/day) are used. Macular changes may progress after drug is discontinued. These agents concentrate in pigmented tissue[97]
Ethambutol	Retrobulbar neuritis	At dosages of 15 mg/kg/day, virtually void of ocular side effects. Such effects are rare at dosages of 25 mg/kg/day for a duration of a few months. Patients treated for prolonged periods should have routine visual examinations including visual fields. Most effects are reversible after the drug is discontinued, but optic neuritis may continue to progress for 1–2 months after the drug has been discontinued[97,102]
Gentamicin	Pseudotumor cerebri	Rare, but has been well documented with secondary papilledema and visual loss[97]

Drug Class	Effect(s)	Clinical Remarks
Linezolid	Optic neuropathy	Blurry vision progressing to optic neuropathy and blindness has been reported rarely, most often in patients taking linezolid for >28 days of therapy. Ophthalmic adverse effects were reversible upon discontinuation.[106]
Nalidixic acid	Visual sensations	Most common ocular side effect. Main feature is a brightly colored appearance of objects; occurs soon after the drug is taken. Although quinolone antibiotics are nalidixic acid derivatives, they have rarely been associated with these ocular side effects.[97]
	Visual loss	Temporary effect (30 minutes–3 days)
	Papilledema	Primarily in infants and young children and secondary to intracranial pressure; reversible on withdrawal of the drug
Sulfonamides	Myopia	Acute and reversible; most common ocular side effect[97]
	Conjunctivitis	Primarily with topical sulfathiazole, 4% incidence between 5 and 9 days of therapy[97]
	Optic neuritis	Even in low dosages. Usually reversible with complete recovery of vision[97]
	Photosensitivity	Associated with use of sulfisoxazole lid margin therapy[107,108]
Voriconazole	Altered visual perception	May be associated with higher doses or plasma concentrations[109]
	Blurred vision	
Anti-Inflammatory Agents (Also See Analgesics; Corticosteroids)		

Drug Class	Effect(s)	Clinical Remarks
Gold	Corneal Conjunctival deposits	Deposition in the conjunctiva and superficial cornea more common than in the lens or deep cornea. Incidence in cornea of 40%–80% in total doses of 1.5 g; visual acuity is unaffected. One reported case after oral therapy[97]
Indomethacin	Decreased vision	Rare; also changes in color vision have been rarely reported.[97]
Phenylbutazone	Decreased vision	Most common ocular side effect with this drug may be caused by lens hydration.[97]
	Conjunctivitis retinal hemorrhage	Occurs less often than vision. The conjunctivitis may be associated with development of Stevens–Johnson syndrome or an allergic reaction[97]
Antineoplastic Agents		
Busulfan	Cataracts	Reported with high dosages[97]
Carmustine	Arterial narrowing Nerve fiber layer infarcts Intraretinal hemorrhages	These ocular side effects are not well established. Evidence of delayed bilateral ocular toxicity developed in 2 of 50 patients treated with high-dose IV carmustine (800 mg/m^2). Symptoms of ocular toxicity became evident 4 weeks after IV treatment. Evidence of delayed ocular toxicity (mean onset 6 weeks) ipsilateral to the site of infusion developed in 7 of 10 patients treated with intra-arterial carotid doses of carmustine to a cumulative minimum of 450 mg/m^2 in two treatments[110]
Cytarabine	Keratoconjunctivitis Ocular burning Photophobia Blurred vision	Corneal toxicity and conjunctivitis have been reported with high-dose (3 g/m^2) therapy[111]

Drug Class	Effect(s)	Clinical Remarks
Doxorubicin	Conjunctivitis	May last for several days after treatment[97]
	Excessive tearing	
Erlotinib	Trichomegaly and ocular irritation	
Fluorouracil	Ocular irritation	Reversible and seldom interfere with continued therapy[97]
	Lacrimation	
Tamoxifen	Corneal opacities Decreased vision Retinopathy	Generally occurs in patients receiving >1 year of treatment when a total dose exceeding 100 g has been taken[97]
Vinca alkaloids (especially vincristine)	Extraocular muscle paresis (EMP) Ptosis	The onset of EMP or paralysis may be seen as early as 2 weeks. Dose related. Most recover fully when drug is discontinued[97]
Barbiturates		
	Miosis Mydriasis Disturbances in ocular movement Ptosis	Most significant ocular side effects occur in chronic users or in toxic states. Pupillary responses are variable; miosis seen most frequently, except in toxicity when mydriasis predominates. Nystagmus and weakness in extraocular muscles may be seen. Chronic abusers have a characteristic ptosis[95]
Bisphosphonates (Alendronate, Etidronate, Pamidronate, Risedronate)		
	Blurred vision, pain, photophobia, conjunctivitis, scleritis, uveitis	Adverse events more common with pamidronate. Scleritis and uveitis are of greatest concern. After persistent reduction in vision of sustained ocular pain, refer patient to an ophthalmologist. Ocular NSAID treatment may be of symptomatic benefit[102]
Corticosteroids		

Drug Class	Effect(s)	Clinical Remarks
	Cataracts	Posterior subcapsular cataracts have been associated with systemic corticosteroids in patients who have received >15 mg/day of prednisone or its equivalent daily for periods >1 year.[112,113] Rare reports of bilateral posterior subcapsular cataracts associated with nasal aerosol or inhalation of beclomethasone dipropionate have been received. Most patients had received therapy for >5 years, often in higher than the recommended dosage. Approximately 40% of patients were also receiving systemic corticosteroids.[114]
	↑ Intraocular pressure (IOP)	More common with topical corticosteroids than with systemic therapy. Of little consequence in patients without preexisting glaucoma. Patients with glaucoma should be monitored routinely if receiving systemic corticosteroids[97] (see Case 54-8, Question 2).
	Papilledema	Intracranial hypertension or pseudotumor cerebri from systemic corticosteroids has been well documented. The incidence appears to be greater in children than in adults; primarily associated with chronic therapy
Digitalis		

Drug Class	Effect(s)	Clinical Remarks
	Altered color vision, visual acuity	Changes in color vision. A glare phenomenon and a snowy appearance in objects have been associated primarily with digitalis intoxication. In a small number of cases, reversible reduction in visual acuity has been noted. Also associated with changes in the visual fields.[97]
	Decreased IOP	Digitalis derivatives can decrease IOP, but clinical use for glaucoma is not practical because the therapeutic systemic dose for this effect is very near the toxic dose.[97]
Diuretics		
Carbonic anhydrase inhibitors	Myopia	Acute myopia that may last from 24 to 48 hours. Probably caused by an increase in the anteroposterior diameter of the lens, which may be reversible even if drug use is continued.[97]
Thiazides	Myopia	Thiazide diuretics have been associated with acute myopia that may last from 24 to 48 hours[97,98]
Estrogens		
Clomiphene	Blurred vision Mydriasis Visual field changes Visual sensations	5%–10% experience ocular side effects. Blurred vision is the most common effect, although visual sensations such as flashing lights, distortion of images, and various colored lights (primarily silver) may occur.[97]
Immunomodulators		
Imatinib	Visual deficits	Ocular symptoms include blurred vision, conjunctivitis, dry eyes, epiphora, and periorbital edema. The latter occurs in up to 74% of treated patients.[115]

Drug Class	Effect(s)	Clinical Remarks
Interleukin-2	Visual deficits	Interleukin-2 visual complications have occurred during the first or second treatment cycle, usually within 5–6 days of initiation of therapy. Ocular symptoms included diplopia, binocular negative scotomas (isolated areas of varying size and shape in which vision is absent or depressed; these are not perceived ordinarily but would be apparent on completion of a visual field examination), and palinopsia (abnormal recurring visual imagery). In most cases, treatment was continued for the entire planned duration of therapy. Symptoms resolved after discontinuation.[116]
Phenothiazines		
Chlorpromazine	Deposits on the lens	Rare when total dose <0.5 kg. Visible after a total dose of 1 kg in most cases; incidence may increase to 90% after ≥2.5 kg. Usually, deposits do not affect vision appreciably. The cornea and conjunctiva may be affected after the lens shows pigment changes.[97]
PDE-5 inhibitors Sildenafil Tadalafil Vardenafil	Changes in color or light perception, blurred vision, conjunctival hyperemia, ocular pain, photophobia	Color vision alterations are mild to moderate. Blurred vision does not impair visual acuity. Visual alterations usually subside within 4 hours after the dose.[117–119] Ocular adverse effects are uncommon, dose dependent, and fully reversible to date. Incidence is not related to age but is related to blood concentration. Peak visual effects usually occur within 60 minutes after ingestion.[102]

Drug Class	Effect(s)	Clinical Remarks
α_1 Antagonists Prazosin Terazosin Doxazosin Alfuzosin Tamsulosin Silodosin	Blurry vision Intraoperative floppy iris syndrome	Approximately 1%–3% of patients taking second-generation α_1 antagonists (prazosin, terazosin, doxazosin, alfuzosin) have reported blurry vision. α_1 Antagonists have been associated with intraoperative floppy iris syndrome, a potential complication of cataract surgery. Patients should notify their ophthalmologist if they take α_1 antagonists currently or did so in the past.[120–125]
Retinoid		
Isotretinoin	Dry eyes, blepharoconjunctivitis optic neuropathy, vision disturbances	Approximately one-third of patients report dry or irritated eyes when taking isotretinoin. Higher doses of 1–2 mg/kg are associated with blepharoconjunctivitis (20%–43% of patients experiencing). Decreased night vision, optic neuropathy, and vision disturbances have been reported by clinical trial participants and in postmarketing surveillance.[126,127]

CNS, central nervous system; NSAID, nonsteroidal anti-inflammatory drug.

OCULAR EMERGENCIES

Chemical Burns

CASE 54-4

QUESTION 1: S.J., a 24-year-old construction worker, has splashed an unidentified chemical in his eyes and runs into a nearby pharmacy for burning in both eyes.

Should the pharmacist attempt to treat S.J. or refer him to the emergency department?

Chemical burns require immediate attention. The immediate treatment is copious irrigation using the most accessible source of water (eg, shower, faucet, drinking fountain, hose, bathtub). After at least 5 minutes of initial irrigation, S.J. should be taken immediately to the emergency department. A water-soaked towel or cloth should be kept on his eyes during transport.

Other Ocular Emergencies

When health care professionals are approached by patients with acute ocular emergencies (eg, chemical burns, corneal trauma, corneal ulcers, acute angle-closure glaucoma), patients require immediate treatment and should be referred to an ophthalmologist if the practitioner has even the slightest doubt about appropriate therapy. It is difficult to effectively evaluate the severity of ocular disorders without the benefit of a thorough ophthalmologic workup and specialized training. In situations of corneal trauma from abrasion or foreign bodies, the patient often has a gritty, scratchy feeling and can be aware of a foreign body's presence. The corneal tissue is an excellent culture medium for bacteria (eg, *Pseudomonas aeruginosa*), and therapy should be initiated as soon as possible to avoid corneal perforation and possible blindness.[1] Signs and symptoms of acute angle-closure glaucoma are reviewed in Case 54-2, Question 1.

Gonococcal conjunctivitis is an ocular emergency, and patients should be referred immediately to an ophthalmologist to minimize the potential of corneal perforation.[1] These patients, who can present with symptoms of red, tender, swollen eyelids with exophthalmos and mild pain, may be suffering from orbital cellulitis or endophthalmitis, which require immediate treatment with systemic antibiotics. Conjunctivitis of other origins (see Acute Bacterial Conjunctivitis [Pinkeye] and Allergic Conjunctivitis sections) generally is not an ocular emergency.

Any loss of vision (whether sudden, complete, or transient), flashes of light, pain, or photophobia can signify potentially damaging ocular disorders (eg, retinal artery occlusion, optic neuritis, amaurosis fugax, retinal detachment), and an ophthalmologist should evaluate the patient as soon as possible. Referral is also recommended for patients with blurred vision, pupil disorders, diplopia, nystagmus, or ocular hemorrhage.

COMMON OCULAR DISORDERS

Dry Eye Disease (Keratoconjunctivitis Sicca)

Dry eye disease is one of the most common ocular disorders. Global prevalence ranges from 5% to 50%.[128] Based on data from the National Health and Wellness Survey, 6.8% of the U.S. adult population have been diagnosed with dry eye disease. The prevalence increases with age (2.7% in those age 18–34 years vs 18.6% in those age ≥75 years or older) and is higher in females than males (8.8% vs 4.5%).[129] Dry eye disease is a multifactorial chronic disease of the corneal surface associated with persistent symptoms of foreign-body sensation, irritation, burning, redness, photosensitivity, and intermittent blurred vision. Dry eye disease is often associated with reduced or abnormal tears and inflammation of the ocular surface. Risk factors include advancing age, female sex, low humidity environments, systemic medications, and autoimmune disorders.[128] Initial therapies to relieve symptoms include warm compresses, tear replacement (ie, over-the-counter [OTC] artificial tears), reducing environmental causes, discontinuing medications that cause or worsen dry eye, and improved nutrition. Most patients require long-term use of nonprescription tear replacements, and, if these are not sufficient, other treatments are prescribed. These treatments include ophthalmic anti-inflammatory agents (eg, fluorometholone and/or cyclosporine eye drops), punctal occlusion, systemic cholinergic agents, and autologous serum tears.[130] In July

2016, the FDA approved lifitegrast (Xiidra®) ophthalmic solution) for the treatment of signs and symptoms of dry eye disease. Lifitegrast is the first medication in a new class of drugs, called lymphocyte function–associated antigen 1 (LFA-1) antagonist. Lifitegrast is preservative free, comes in unit vials, and is dosed twice daily. Side effects include transient instillation site burning, blurred vision, and unpleasant or distorted taste.[131]

Stye (Hordeolum)

Styes are infections of the hair follicles or sebaceous glands of the eyelids. They present as well-defined, painful lumps at the eyelid margin.[132] The most common infecting organism is *Staphylococcus aureus.* Most styes resolve spontaneously over days to weeks with treatment of warm compresses and massage. OTC products should not be recommended. An ophthalmologist should evaluate styes that do not respond to warm compresses within a few days.

Conjunctivitis

Conjunctivitis, a common external eye problem that involves inflammation of the conjunctiva is usually associated with symptoms of a diffusely reddened eye with purulent or serous discharge accompanied by itching, smarting, stinging, or a scratching foreign-body sensation.[133] Patients with pain, decreased vision, unequal distribution of redness, irregular pupils, or opacity should be referred immediately to an ophthalmologist because these are signs of more serious eye disease.

Conjunctivitis can be bacterial, fungal, parasitic, viral, or allergic in origin. Most cases of bacterial conjunctivitis are caused by *S. aureus, Streptococcus pneumoniae*, and *Haemophilus influenzae*, although a number of other organisms may be responsible.[134] The infection usually starts in one eye and is spread to the other by the hands. It is highly contagious, and patients should be advised to wash their hands frequently with soap and water, avoid sharing

personal items with others, and to discard multiple-dose eye drop containers if inadvertent contact with the eye occurs. Unlike bacterial conjunctivitis, corneal infections can obliterate vision rapidly; therefore, accurate diagnosis is important.

VIRAL CONJUNCTIVITIS

Viral conjunctivitis is the most common cause of infective conjunctivitis, accounting for 80% of all acute conjunctivitis.[135] Usually self-limiting, adenovirus is the reported cause in 65% to 90% of viral conjunctivitis cases. Other causes include enterovirus, herpes simplex virus, varicella-zoster virus, Epstein–Barr virus, and influenza. Adenoviral conjunctivitis is characterized by a sudden onset and, often, bilateral symptoms of watery discharge, redness, chemosis, and eyelid swelling. Topical antibiotics are not needed to treat adenovirus conjunctivitis and should be avoided owing to their own risks for adverse effects, toxicity, and cost to the patient. Symptomatic treatment may include artificial tears, topical antihistamines, and cold compresses. In severe cases involving ocular complications, topical corticosteroids may be used.

ACUTE BACTERIAL CONJUNCTIVITIS

CASE 54-5

QUESTION 1: L.T. is a 6-year-old boy with diffuse bilateral conjunctival redness that has been present for 2 days. A crusting discharge is deposited on his lashes and the corners of his eyes. His vision is normal, and his pupils are round and equal. The diagnosis of acute bacterial conjunctivitis is made, and sodium sulfacetamide 10% ophthalmic drops, two drops in both eyes every 2 hours while awake, are prescribed.

What other measures should be used? What instructions should his caregivers receive?

Treatment of acute typical bacterial conjunctivitis such as this is usually empirical. Other ophthalmic antibiotic drops or ointments, such as neomycin-polymyxin B-gramicidin combination or polymyxin B-trimethoprim (Polytrim®), are also used in these situations.

Although other antimicrobials, such as the ocular quinolones, may be used for bacterial conjunctivitis, these agents should be reserved as second-line therapies because of cost and the potential development of resistance. Proper management of this infection also includes mechanical cleaning of the eyelids and hygienic measures that prevent spreading the infection to other children. The deposits should be removed as often as possible with moist cotton swabs or cotton-tipped applicators. A mild baby shampoo can be used to moisten the applicator. Firm-adherent crusts may be softened with warm, moist compresses. Because this material is infectious, it should be disposed of in a sanitary manner. The common use of washcloths by several individuals will spread bacterial conjunctivitis.

ALLERGIC CONJUNCTIVITIS

CASE 54-6

QUESTION 1: N.V., a 10-year-old girl, has experienced redness in both eyes accompanied by "hay fever" for the past 2 months (June and July). There is no crusting on her eyelids, and her vision is normal; she rubs her eyes often because they itch.

What treatment is best for N.V.'s allergic conjunctivitis?

Allergic conjunctivitis is an immunologic inflammatory process of the eye.[133,136] Typically, it initially presents in late childhood or early adulthood as redness, tearing, itching, and foreign-body sensation. Mild disease is managed conservatively by avoiding allergens, irritants, and rubbing the eyes. Patients may use cold compresses, artificial tears, and air filtration systems for relief. For patients with moderate-to-severe disease, pharmacologic treatment is indicated. First-line treatment includes topical antihistamines, mast cell stabilizers, and dual-action agents.

Ophthalmic antihistamines relieve itching and redness and tend to provide a faster response compared to oral antihistamines, but have a limited duration of action and require more frequent dosing.[133,136] They should not be used by patients at risk for angle-closure

glaucoma. They include pheniramine maleate 0.3%/naphazoline 0.025% up to qid (a combination of antihistamine plus vasoconstrictor), epinastine 0.05% bid, and cetirizine (Zerviate®) 0.24% bid. Mast cell stabilizers include nedocromil (Alocril®) 2% bid, cromolyn 4% qid to six times daily, and lodoxamide tromethamine (Alomide®) 0.1% up to qid. These agents take about 3 to 5 days to start working but may be useful for prophylaxis or for patients who did not tolerate topical antihistamines. Dual-action agents that have both antihistamine plus mast cell–stabilizing effects have become the treatment of choice owing to their multiple symptomatic benefits. Medications in this class include ketotifen 0.025% bid, alcaftadine (Lastacaft®) 0.25% daily, bepotastine (Bepreve®) 1.5% bid, and olopatadine (Patanol®/Pataday®) 0.1% bid and 0.2% daily. Adverse effects of all the agents in this section include chemosis, headache, bloodshot eye appearance, rhinitis, nasopharyngitis, nasal congestion, bitter taste, and eye irritation, such as burning, stinging, redness, and pruritis.

Other treatments for allergic conjunctivitis include ocular decongestants, ocular nonsteroidal anti-inflammatory drugs (NSAIDs), ocular steroids, intranasal corticosteroids, oral antihistamines, and allergen immunotherapy.[133,136] Ocular decongestants (vasoconstrictors) are typically used in conjunction with antihistamines and mast cell stabilizers. They can cause rebound vasodilation with continued use, so they should be limited to short-term treatment. They should not be used in patients at risk for angle-closure glaucoma and should be used with caution in patients with cardiovascular disease, hyperthyroidism, and diabetes. Ocular NSAIDs and steroids may have a role in patients who are unresponsive to other therapies, with moderate-to-severe symptoms, or repeated exposure to allergens. Patients who wear contact lenses, have herpes simplex virus eye disease, have symptoms that do not improve with treatment, or who are experiencing vision loss, photophobia, or eye pain or discharge should be referred for evaluation with an ophthalmologist.

Corneal Ulcers

CASE 54-7

Question 1: T.S. presents with a diagnosis of bacterial corneal ulcer in the right eye and prescriptions for "fortified gentamicin" and cefazolin eye drops, which are not commercially available.

What is the rationale for this therapy, and how can the patient obtain it?

The initial choice of therapy for bacterial corneal ulcers commonly is based on a Gram stain and clinical impression of the severity of the ulcer.[137] Monotherapy with a fluoroquinolone eye drop or combination therapy with fortified topical antibiotics can be prescribed. *Fortified antibiotics* refers to preparation of a concentration that is higher than in commercially available topical antibiotics.

Commonly prescribed products include bacitracin 5000 to 10,000 units/mL, cefazolin 33 to 100 mg/mL, gentamicin or tobramycin 9.1 to 13.6 mg/mL, and vancomycin 25 to 50 mg/mL.[137] Fortified gentamicin has been prepared by adding 80 mg of parenteral gentamicin to the commercially available gentamicin ophthalmic solution. The final concentration of this solution is 13.6 mg/mL. Cefazolin ophthalmic solution is prepared by reconstituting 500-mg parenteral cefazolin with 2 mL of sterile normal saline. Two milliliters of artificial tears solution is removed from a commercially available 15-mL bottle and replaced with the 2-mL reconstituted cefazolin solution (resulting in a final cefazolin concentration of 33 mg/mL). Therapy initially can be administered as frequently as every 15 to 30 minutes with extension of intervals as the ulcer resolves.[138] The preparation of extemporaneously compounded ophthalmic products must adhere to established federal and state agency guidelines and must address quality control concerns (eg, pH, tonicity, sterility, particulate matter). The formulation of sterile products should not be undertaken without due consideration of well-established practice standards.

OPHTHALMIC CORTICOSTEROIDS

Comparison of Preparations and Clinical Use

CASE 54-8

QUESTION 1: S.S. has undergone cataract extraction from his left eye. Prednisolone acetate 1% administered qid has been prescribed.
Is prednisolone acetate an appropriate choice?

The topical ophthalmic corticosteroid preparations are described in **Table 54-4**. The salt form affects the ability of the preparation to penetrate the cornea. For example, biphasic salts penetrate the intact cornea better than water-soluble salts. The ability of a formulation to penetrate the cornea, however, does not indicate increased therapeutic effectiveness. Prednisolone acetate 1% and fluorometholone acetate 0.1% have the best anti-inflammatory effects.[139–141] The most commonly prescribed ophthalmic corticosteroid is prednisolone acetate because of its availability in generic form and generally lower cost.

Table 54-4
Ophthalmic Corticosteroids and Relative Potency

High Potency	Difluprednate 0.05% (Durezol®) Fluorometholone acetate 0.1% (Flarex®) Prednisolone acetate 1% (Pred Forte®)
Intermediate Potency	Dexamethasone alcohol 0.1% (Maxidex®) Fluorometholone 0.1% (FML) Fluorometholone 0.25% (FML Forte®) Lotreprednol 0.2% (Lotemax®) Loteprednol 0.5% (Alrex®) Prednisolone acetate 0.12% (Pred Mild®) Prednisolone sodium phosphate 1%
Low Potency	Dexamethasone phosphate 0.1% Medrysone 1% (HMS)

Topical ophthalmic corticosteroids are used for a variety of conditions associated with inflammation of the conjunctiva, cornea, and within the anterior segment of the eye. They are generally contraindicated in individuals with active ocular varicella, vaccinia, herpes simplex, and mycobacterial infections.

Adverse Effects

INCREASED INTRAOCULAR PRESSURE

Case 54-8, Question 2: S.S. continued using topical prednisolone acetate 1%, one drop in the left eye qid for 8 weeks. Before therapy, the IOPs in both eyes were 16 mm Hg, but on the last follow-up visit, his IOP was 16 mm Hg in the right eye and 26 mm Hg in the left eye. How do you assess these observations?

S.S.'s elevated IOP could be related to topical steroid therapy. In one study, the ophthalmic administration of corticosteroid preparations (**Table 54-5**) increased IOP in three genetically distinct subgroups.[112,113,142] Fluorometholone acetate increased IOP by >10 mm Hg in known steroid responders in 29.5 days (median), whereas dexamethasone did the same in 22.7 days (median).[143] In a retrospective follow-up, 13% of high-corticosteroid responders developed POAG, and 63.8% developed ocular hypertension. No low responders developed POAG, and only 2.4% developed ocular hypertension.[143] Although corticosteroid-induced increases in IOP are associated most frequently with topical ophthalmic preparations, systemic corticosteroids may cause a similar response, although the magnitude is somewhat less.[144] The risk for corticosteroid-induced ocular hypertension is higher in patients with high myopia, diabetes mellitus, or connective tissue disease (particularly rheumatoid arthritis).

Table 54-5
Intraocular Pressure Response to Topical Steroids in Random

Populations

Author	Parameter of Response	Number of Subjects	Low	Medium	High	Mean
Armaly[113]	Increase of pressure in eye medicated with 0.1% dexamethasone	80	<5 mm Hg 66%	6–15 mm Hg 29%	16 mm Hg 5%	5.5 mm Hg
Becker and Ballin[142]	Final pressure in eye medicated for 6 weeks with 0.1% betamethasone	50	<19 mm Hg 70%	20–30 mm Hg 26%	32 mm Hg 4%	17.0 mm Hg
	Time to maximal response		2 weeks	4 weeks	4 weeks	

Topical corticosteroids exert their effects by decreasing aqueous humor outflow, whereas systemic corticosteroids may increase aqueous humor production.[144] The effects on IOP apparently are unrelated to the ability of the corticosteroid to penetrate the cornea. Dexamethasone has been associated with the greatest IOP increase.[145] Fluorometholone, medrysone, rimexolone, and loteprednol have been associated with lower, although sometimes significant, increases in IOP.[146–148] The pressure response is often reversible when the offending agent is discontinued. In subjects with prolonged IOP elevation, glaucomatous field defects are more likely to develop in corticosteroid-responsive patients.[149]

CATARACTS

CASE 54-9

QUESTION 1: G.A., who had asthma, has been taking prednisone 10 mg/day for 1 year. A routine ophthalmic examination revealed early cataract formation. Why could this be related to the prednisone?

Systemic and topical ophthalmic corticosteroids have been associated with the development of cataracts. About 23% of patients treated with 10 to 16 mg/day of prednisone orally (or its equivalent dose) for 1 year or more developed posterior subcapsular cataracts (PSCs).[150,151] The estimated occurrence of PSC in patients treated with >16 mg/day of prednisone for more than a year increased to >70% during the same period. Patients receiving <10 mg/day prednisone or its equivalent are unlikely to develop PSC, although some contend that the concept of a “safe” dosage should be

abandoned because of variable patient sensitivity to this side effect.[152] As illustrated by G.A., the cataracts cause few subjective problems and little measurable decrease in visual acuity. Although systemic corticosteroids are primarily implicated, the use of topical corticosteroids has also been associated with PSC formation.[153] Patients treated with alternate-day dosing of oral corticosteroids may be at lower risk for PSC formation.[154] Any patient receiving long-term corticosteroids should receive routine ophthalmic follow-up.

SYSTEMIC SIDE EFFECTS FROM OPHTHALMIC MEDICATION

CASE 54-10

QUESTION 1: J.F., a 62-year-old female, received one drop of phenylephrine 10% in each eye to dilate the pupils. Shortly after administration, her blood pressure increased to 210/130 mm Hg for 5 minutes, and she became confused.

How common is this type of reaction in patients receiving topical phenylephrine? What other topical ophthalmic medications have been associated with systemic effects?

In 33 cases, possible adverse effects have been associated with topical phenylephrine 10%.[155] In a double-blind study, no statistically significant differences were observed in blood pressure or pulse rate between experimental and control groups when phenylephrine 10% or tropicamide (Mydriacyl®) 1% was administered to 150 patients.[156] Nevertheless, care should be taken when phenylephrine 10% is administered in patients with hypertension or cardiac abnormalities in whom systemic absorption could be hazardous. No similar reports have been associated with topical use of phenylephrine 2.5%.

In addition to the systemic effects from topical administration of cholinergic agents, epinephrine, and timolol that were previously described, topical atropine, cyclopentolate (Cyclogyl®), and

scopolamine have been associated with psychosis.[157–159] Fatalities have been associated with topical atropine,[160] ataxia has occurred with topical homatropine, and one case of unconsciousness with tropicamide was reported.[161]

Topical chloramphenicol-polymyxin-B sulfate ophthalmic ointment has been associated with bone marrow aplasia after intermittent use for 4 months.[162] A Cushingoid reaction has been reported in a 30-month-old baby girl treated with dexamethasone alcohol (Maxidex®) qid in both eyes for 14 months.[163]

The administration of ophthalmic prostaglandins and PGAs is associated with systemic side effects (see Table 54-1).

OCULAR NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

CASE 54-11

QUESTION 1: W.A. is scheduled to undergo cataract extraction with implantation of an intraocular lens. Preoperative orders include administration of flurbiprofen 0.03% to inhibit intraoperative miosis. The formulary includes only diclofenac 0.1%.

Is this a suitable alternative to flurbiprofen?

Commercially available ophthalmic NSAIDs (eg, bromfenac, diclofenac, flurbiprofen, ketorolac, and nepafenac) share a similar mechanism of action involving inhibition of prostaglandin synthesis and reduction of prostaglandin-mediated ocular effects.[164] Minor clinical differences, which probably insignificant, exist, and approved indications differ (**Table 54-6**).[165–172] These agents are generally well tolerated, but they can cause transient burning and stinging on instillation. Diclofenac is not approved for the prevention of intraoperative miosis, but various dosage regimens have been reported as effective for this use.

Table 54-6
Ocular Nonsteroidal Anti-inflammatory Drugs

Indication	Drug/Approval Status for Indication	Dosage(s)
Inhibition of intraoperative miosis	Diclofenac 0.1% (Voltaren®, U)[165]	Three reported regimens; one drop every 15–30 minutes for four doses; one drop tid for 2 preoperative days; one drop at 2 hours, 1 hour, and 15 minutes before surgery
	Flurbiprofen 0.03% (Ocufen®, A)[166]	One drop every 30 minutes for 2 hours before surgery
	Ketorolac 0.5% (Acular, U)	One drop every 15 minutes beginning 1 hour before surgery
Anti-inflammatory after cataract surgery	Bromfenac 0.09% (Xibrom™, A)	One drop bid beginning 24 hours after surgery and continuing through the 2 weeks of the postoperative period
	Diclofenac 0.1% (A)[167] Nepavanac 0.1% (Nevanac™, A)	One drop bid to qid, including 24 hours preoperative administration. One drop tid beginning 1 day before cataract surgery, continued on the day of surgery and through the first 2 weeks of the postoperative period
	Ketorolac 0.5% (A)[168]	One drop tid, including 24 hours preoperative administration
Prevention/treatment of cystoid macular edema	Diclofenac 0.1% (U)[169]	Two drops five times preoperatively followed by one drop three to five times daily
	Ketorolac 0.5% (U)[168,170]	One drop tid or qid, including 24 hours preoperative administration
Ocular inflammatory conditions (iritis, iridocyclitis, episcleritis)	Diclofenac 0.1% (U)	One drop qid
Seasonal allergic/vernal conjunctivitis	Bromfenac 0.1% (U)	One drop bid

Indication	Drug/Approval Status for Indication	Dosage(s)
	Diclofenac 0.1% (U)	One drop every 2 hours for 48 hours; then qid
	Ketorolac 0.5% (A)[171,172]	One drop qid

A, approved use; bid, twice daily; qid, four times a day; tid, three times a day; U, unapproved use.

OCULAR HERPES SIMPLEX VIRUS INFECTIONS

CASE 54-12

QUESTION 1: P.B., a 34-year-old male, presents with a 2-week history of a red, irritated left eye with watery discharge. Recently, vision in his left eye became blurred, and he has light sensitivity. A slit-lamp examination with rose bengal stain revealed a multibranched corneal epithelial defect. This dendritic ulcer is the hallmark of ocular herpes simplex (type 1) infection.

What is the therapy of choice for P.B.?

Ocular herpes is common and can be caused by herpes simplex virus or, less commonly, by the varicella-zoster virus (herpes zoster ophthalmicus). Herpes simplex of the eye typically affects the eyelids, conjunctiva, and cornea, and patients often present with symptoms of pain, tearing, eye redness, sensitivity to light, and irritation or a foreign-body sensation. When herpes affects the epithelium of the cornea (herpes keratitis), it generally heals without scarring. Occasionally, deeper layers of the cornea are affected (stromal keratitis), and scarring can lead to blindness. Trifluridine is the drug of choice for P.B.

Trifluridine

In vitro, the mechanism of action of trifluridine is similar to that of idoxuridine (IDU). Trifluridine also inhibits thymidylate synthase, an enzyme required for DNA synthesis.

For the treatment of ocular herpes, one drop of trifluridine 1% ophthalmic solution should be instilled into the affected eye every 2 hours while awake with a maximal daily dose of nine drops. After reepithelialization, application of trifluridine should be continued for an additional 7 days at a reduced dosage of one drop every 4 hours while awake with a minimum of five drops daily. Continuous administration for periods exceeding 21 days is not recommended because of potential ocular toxicity.

Approximately 96% of treated herpetic corneal ulcers heal within 2 weeks.[173] Therapeutic levels of trifluridine can be found in the aqueous humor after topical administration of a 1% solution, enhancing its possible effectiveness in the treatment of stromal keratitis and uveitis. Trifluridine is also effective in treating herpes simplex virus infections resistant to IDU or vidarabine.

Despite the apparent superiority of trifluridine compared with its antiviral predecessors (IDU, vidarabine), it is not without disadvantages. Trifluridine is activated by uninfected corneal cells and is incorporated into cellular as well as viral DNA. Punctate lesions in the corneal epithelium are clinical manifestations of trifluridine cytotoxicity.[174] However, these effects seem to occur less often with trifluridine than with IDU and vidarabine.

Acyclovir

Acyclovir in in vitro plaque inhibition assays has 5 to 10 times the activity of IDU and trifluridine and >100 times the activity of vidarabine against strains of type 1 and type 2 herpes simplex virus.[175] Acyclovir's apparent superiority lies in its lack of toxicity to normal host cells. In rabbits (rabbit eyes are similar to human eyes), acyclovir 3% ointment healed established herpes simplex epithelial ulcerations at a faster rate and eliminated the virus more effectively than 0.5% IDU and 3% vidarabine ointments.[176] In humans,

ulcerative corneal epithelial lesions appear to respond similarly to acyclovir and IDU.[176] In comparison with IDU, the topical application of acyclovir or trifluridine resulted in a greater proportion of subjects healing within 1 week, and neither was superior for the treatment of dendritic epithelial keratosis.[177] The dose is usually a 1-cm ribbon of ointment instilled five times a day at 4-hour intervals for 14 days or for at least 3 days after healing is completed, whichever is shorter. Detailed dosing instructions are available in product literature of specific manufacturers, and brief reviews of acyclovir and acyclovir resistance are presented in Chapter 77, Opportunistic Infections in Patients Living With HIV, and Chapter 79, Viral Infections.

Other Drugs

Ganciclovir 0.05% and 0.15% gel have been shown to be equivalent to 3% acyclovir ointment in the treatment of superficial herpes simplex keratitis.[178] Cidofovir 1% ointment administered bid was equivalent to trifluridine administered five times daily in the rabbit model.[179] Cidofovir was more efficacious than 3% penciclovir ointment administered bid or qid.[179]

AGE-RELATED MACULAR DEGENERATION

CASE 54-13

QUESTION 1: E.A., a 77-year-old female, informs you she read information from the Internet, and she thinks her symptoms of blurred vision and the need for a bright light to read are consistent with AMD.

Which of the available medicines would be best for her?

AMD is a chronic, progressive disease of the retina that primarily affects patients age 50 years or older. It is characterized by the development of drusen (yellow deposits under the retina made of lipids and proteins), atrophy of the retinal epithelium, and

neovascularization that can lead to vision impairment.[180] It is responsible for an estimated 46% of cases of severe vision loss in persons older than 40 years in the United States. Risk factors for AMD include increasing age, northern European ancestry, genetic factors, and smoking. Commonly referred to as wet AMD, ~20% of patients with AMD have a neovascular form characterized by retinal exudates and hemorrhages originating from under the retina, which increases the risk of central vision distortion, blurring, and blindness. The other form of AMD, referred to as dry, non-neovascular, or atrophic, accounts for the remaining 80% of cases. The disease may be classified as early, intermediate, or advanced (may be neovascular [wet] or non-neovascular [dry]) based on the number and size of drusen that are present and the degree of pathologic abnormality seen on the macula.

Smoking is the most important modifiable risk factor for disease progression, and all patients with AMD who smoke should receive counseling and assistance on smoking cessation.[180] Prospective, randomized controlled clinical trials have shown that in patients with intermediate or advanced AMD, antioxidant vitamins and minerals slow the progression of the disease. The supplements used in the Age-Related Eye Disease Study (AREDS2) included vitamin C 500 mg, vitamin E 400 IU, lutein/zeaxanthin 10 mg/2 mg, zinc oxide 80 or 25 mg, and cupric oxide 2 mg, dosed once daily. Although this combination has shown benefit in patients with intermediate or advanced AMD, it failed to show benefit in patients with early AMD or those with family members who have AMD. Pharmacists may recommend appropriate antioxidant vitamin and mineral supplements to patients with AMD.

Vascular endothelial growth factor (VEGF) is associated with the pathogenesis of choroidal and retinal neovascularization that occurs in patients with advanced, neovascular AMD. VEGF may stimulate neovascularization by influencing endothelial cell proliferation, vascular permeability, and ocular inflammation.[181] Inhibition of VEGF with intravitreal anti-VEGF therapy has become the standard of care for neovascular AMD. The VEGF inhibitors include off-label bevacizumab (Avastin®), ranibizumab (Lucentis®), and aflibercept

(Eylea™).[180–183] All are administered as intravitreal injections by an ophthalmologist. Bevacizumab is a full-length monoclonal antibody that binds all isoforms of VEGF. It is administered as 1.25 mg monthly for 3 months and then monthly or PRN based on ophthalmologic assessment. Ranibizumab is a recombinant, humanized immunoglobulin G1κ isotype therapeutic antibody fragment that inhibits biologic activity of all isoforms of human VEGF-A. The dose is 0.5 mg monthly then PRN based on ophthalmologic assessment. Aflibercept, the newest anti-VEGF for neovascular AMD, is a pan–VEGF-A and placental growth factor inhibitor. It is dosed 2 mg monthly for 3 months and then every 8 weeks thereafter. Clinical studies have shown the anti-VEGF agents to be approximately equal in efficacy. Intravitreal formulations of these medications have been associated with adverse effects, including endophthalmitis infection, intraocular inflammation, intraocular hemorrhage, and rhegmatogenous retinal detachment.[184]

Pain and Its Management

Virginia Ghafoor, Lee A. Kral, and Timothy J. Atkinson

CORE PRINCIPLES		CHAPTER CASES
1	Multimodal perioperative analgesia utilizes neuraxial (epidural or intrathecal) or regional (peripheral nerve) anesthesia in combination with systemic medications to optimize pain control. A preoperative pain assessment is important to identify history of analgesic intolerance, medication contraindications, risks and benefits of neuraxial or regional anesthesia, and the presence of preoperative pain or anxiety.	**Case 55-1 (Questions 1–3)**
2	Intravenous (IV) and oral opioids are used for acute pain management. Risk factors for respiratory depression are important in determining medication selection and dose. Naloxone is the	**Case 55-2 (Questions 1–6)**

	antidote for reversing opioid-induced respiratory depression. Opioid side effects including nausea, vomiting, and constipation require medications for preventative treatment.	
3	Nonopioid medications are the foundation of acute pain management. These medications provide synergistic effects between different classes of analgesics and lower opioid requirements for pain control. Medication options include acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), ketamine, IV lidocaine, and gabapentinoids. Selection of nonopioid medication depends on history of prior use, contraindications, and risk factors for adverse events.	**Case 55-2 (Question 7)**
4	Low back pain is a very common chronic pain condition. It is complex, often involving physical and emotional factors. Patients may have musculoskeletal, neuropathic, and/or central pain that needs to be assessed, as well as comorbidities.	**Case 55-3 (Questions 1, 2)**
5	Chronic pain management requires multimodal therapies, both pharmacologic and nonpharmacologic. Many factors affect analgesic selection, including comorbidities, available routes of administration, and cost.	**Case 55-3 (Questions 3–7)**

6	Neuropathic pain may be caused by injury to peripheral nerves or to the central nervous system (CNS). Neuropathic pain is treated with analgesic antidepressants and anticonvulsants. Peripheral or localized nerve pain may be treated with topical agents.	**Case 55-4 (Questions 1, 2)**
7	Older adults and patients with multiple comorbidities are at high risk for adverse effects from analgesics. Pharmacokinetic and pharmacodynamic drug interactions must be considered with the use of anticonvulsants and antidepressants.	**Case 55-4 (Questions 3, 4)**
8	Functional pain does not have a clear pathophysiology. Comorbid mental health issues and psychosocial stressors complicate chronic pain management. Analgesic antidepressants and anticonvulsants, in conjunction with cognitive-behavioral therapies (CBTs), are recommended for the management of functional pain syndromes (FPSs).	**Case 55-5 (Questions 1, 2)**
9	An open discussion on the benefits and risks of opioid therapy needs to occur frequently with patients. Opioid therapy requires effective risk assessment to avoid medication misuse, opioid use disorder, and diversion. Monitoring recommendations include the use of written opioid agreements, urine drug	**Case 55-6 (Questions 1–6)**

testing, opioid risk screening tools, and electronic prescription monitoring program records.

INTRODUCTION

Pain is defined as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.”[1] The ability to experience pain is critical for survival because it informs the body about real or potential injury (eg, touching a hot stove). The body is then able to respond to the threat and protect itself from further injury (eg, refraining from touching or removing the hand from the hot stove). Pain is a hallmark of many acute and chronic conditions. More than 80% of patients who undergo surgical procedures experience acute pain, 75% of whom report the severity as moderate, severe, or extreme.[2,3] Chronic pain affects >50 million Americans daily, with 19.6 million adults experiencing high-impact chronic pain impeding their ability to work and activities of daily living. The estimated cost to the United States for disability related to chronic pain is estimated at between $560 and $635 billion annually.[4] However, nearly all cases of chronic pain begin as acute pain stemming from surgery, trauma, or illness.[5] Back pain and osteoarthritis (OA) are among the top five chronic pain conditions associated with high health care costs, and the prevalence continues to rise with the aging U.S. population. A study of insurance utilization data for Medicare members from 2007 to 2011 found that annual costs were $327 million for OA and $218 million for back pain.[6] There are also gender, racial, and socioeconomic disparities that exist with chronic pain. Chronic pain is reported more often in females than in males and in non-Hispanic White patients compared with other races and ethnicities.[7] Chronic pain is also more common in those whose income is two times less than the level of poverty. Pain is more complex than just physiology.

It is a subjective experience, and sometimes, the severity of pain does not appear to equal the extent of tissue damage. A person's perception of pain is affected by environmental, emotional, cultural, spiritual, and cognitive factors. Unrelieved chronic pain affects not only physical well-being but also a person's psychological and social well-being and relationships with loved ones. Recent estimates showed that musculoskeletal-related conditions with low back pain, neck pain, and knee OA ranked among the top 10 noncommunicable diseases for global disability-adjusted life years (ie, years of life lost and years lived in disability).[8,9]

Factors that increase pain and suffering include sensory factors, cognitive factors, and emotional factors (**Fig. 55-1**). All are interrelated and illustrate the complex nature of chronic pain.

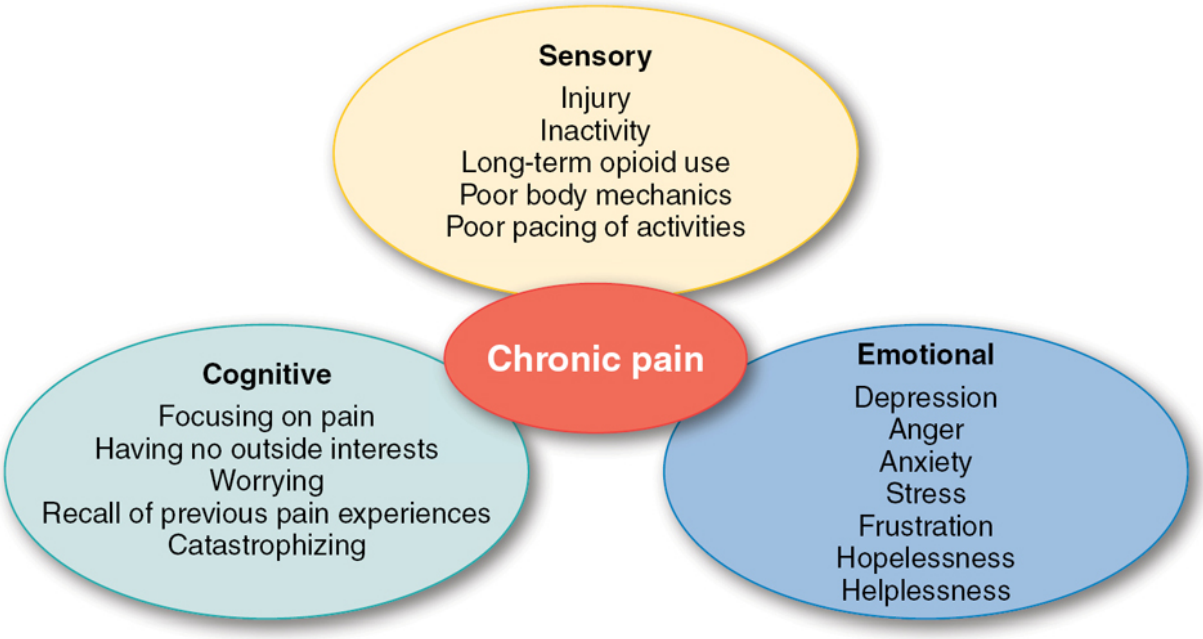

Figure 55-1 Factors affecting chronic pain.

Pathophysiology

ASCENDING PATHWAY

Nociception, or the sensation of pain, is composed of four basic processes: transduction, transmission, modulation, and perception

(**Fig. 55-2**). *Transduction* is the process by which noxious stimuli are translated into electrical signals at peripheral receptor sites (ie, free nerve endings located throughout the skin, muscle, joints, fascia, and viscera). Normal sensory stimuli do not activate the pain signal, but if the stimulus is powerful enough to surpass the threshold for innocuous activation, the receptors become *nociceptors* (ie, pain receptors). These sensory receptors target mechanical (crushing or pressure), chemical (endogenous or exogenous), or thermal (hot or cold) stimuli. Some nociceptors are polymodal, transducing more than one type of stimuli. One of these types of nociceptors is called the transient receptor potential (TRP). This family has a large number of members that are activated by the whole spectrum of thermal stimuli (very hot to very cold), as well as some mechanical and various chemical stimuli. Other receptors are “silent,” but are recruited if the stimulus is more intense or prolonged.

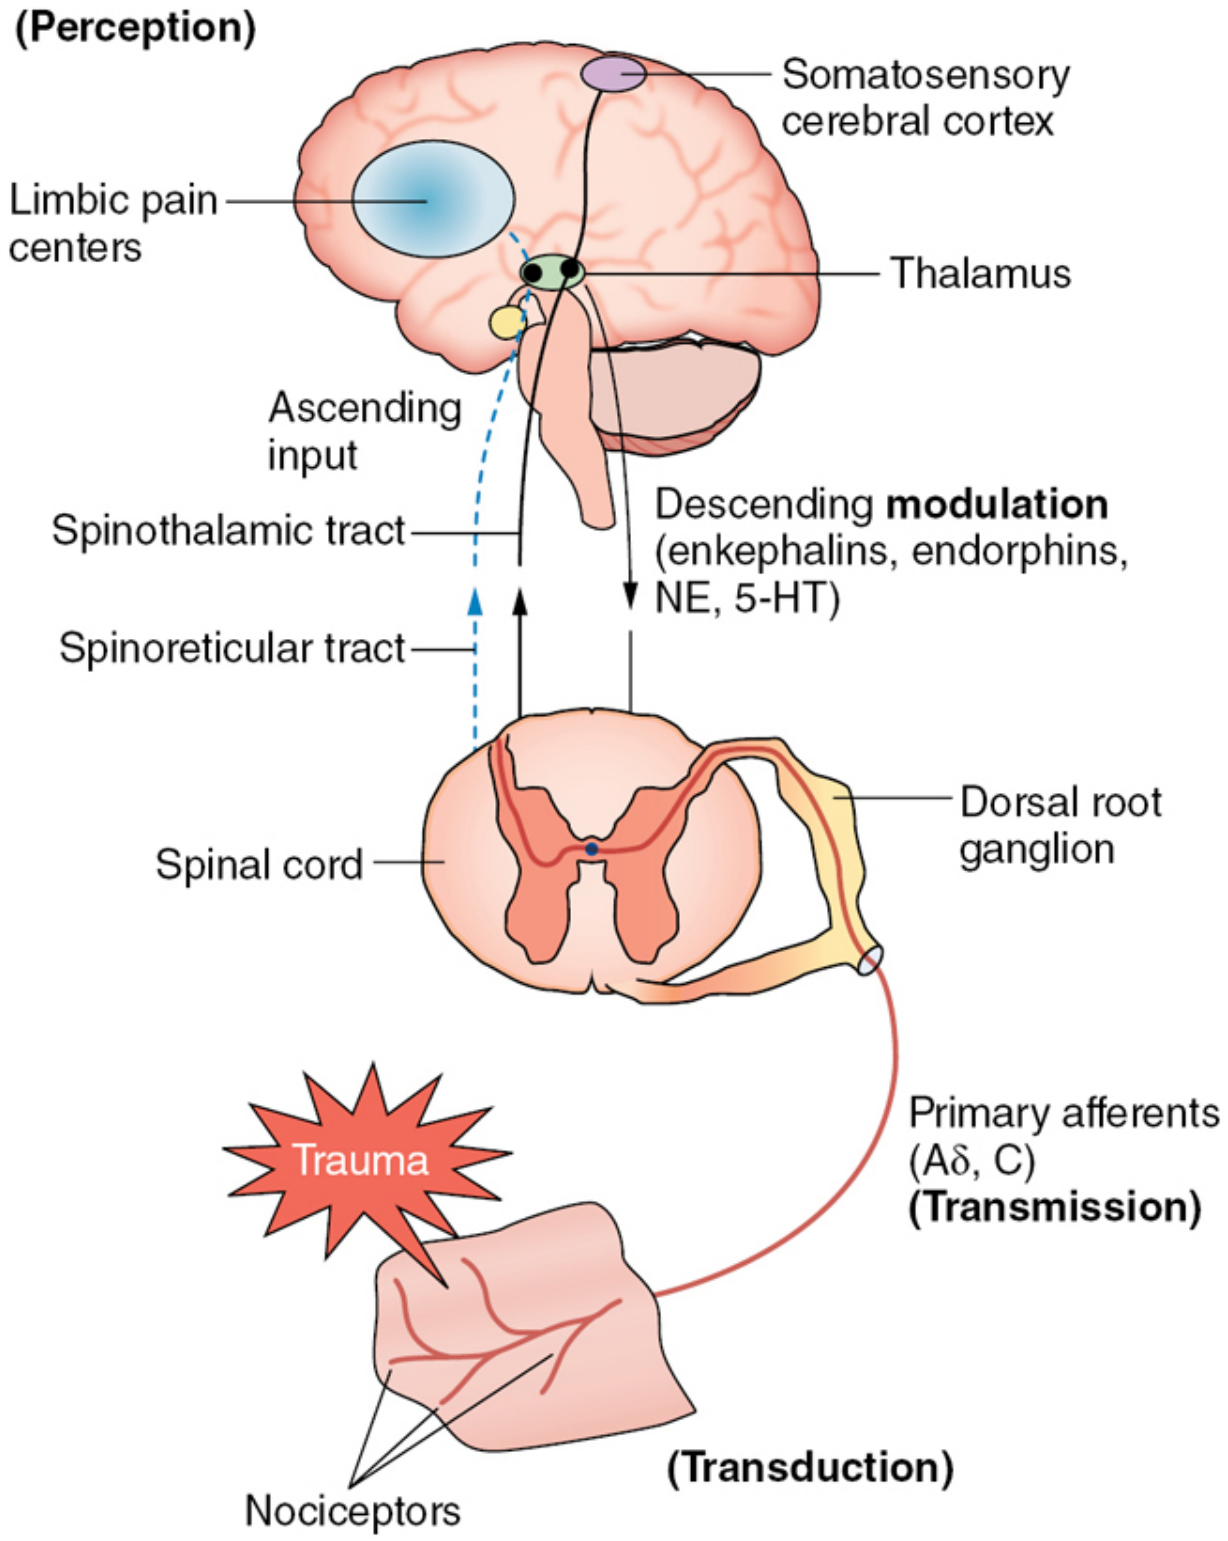

Figure 55-2 Pain pathways. 5-HT, serotonin; NE, norepinephrine.

After stimulation of nociceptors, several processes occur. Pro-inflammatory mediators, including histamine, substance P, prostaglandins, bradykinins, and serotonin, are released at the site of injury. Immune mediators are also released, including tumor necrosis factor, nerve growth factors, interleukins, and interferons. These mediators sensitize the nociceptors, lowering the pain threshold in and around the injury (peripheral sensitization). The sensitized nociceptors may fire more frequently and erratically and are stimulated by much weaker stimuli (hyperalgesia). More frequent firing is correlated with an increase in pain intensity.[10]

Transmission is the propagation of the electrical signal along primary afferent nerves, through the dorsal horn of the spinal cord to the central nervous system (CNS). Painful impulses are generated at the nociceptor, with voltage-gated sodium channels initiating the action potentials. Voltage-gated calcium channels are responsible for allowing calcium influx to the presynaptic terminal, causing neurotransmitter release. The message is then transmitted to the spinal cord via two primary afferent nerve types: myelinated A fibers and unmyelinated C fibers. The Aδ fibers are responsible for rapidly conducting impulses associated with thermal and mechanical stimuli. Transmission of signals along Aδ fibers results in sharp or stabbing sensations that alert the patient to an injury (also called “first pain”). This produces reflex signals, such as musculoskeletal withdrawal, to prevent further injury.[10]

The smaller, unmyelinated C fibers respond to mechanical, thermal, and chemical stimuli but conduct impulses at a much slower rate compared with Aδ fibers. Transmission of electrical impulses via C fibers results in pain that is dull, aching, burning, and diffuse (called “second pain”). Prolonged stimulation of C fibers causes an additive effect on the perceived intensity of second pain, called *windup.*

At the level of the dorsal horn of the spinal cord, the primary afferents cause calcium release into the presynaptic terminal. This leads to the release of excitatory amino acids (EAAs) such as glutamate into the synapse (**Fig. 55-3**). C fibers also release peptides such as substance P, neurokinins, and calcitonin gene–

related peptide (CGRP). The EAAs then stimulate the postsynaptic receptors, and the electrical signals stimulate second-order neurons in the CNS. The postsynaptic α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionate (AMPA) receptors are sodium channel mediated and are responsible for the first pain mentioned previously. *N*-Methyl-D-aspartate (NMDA) receptor channels allow both sodium and calcium passage. Usually, a magnesium ion holds the channels closed; however, when there is sustained firing from the primary afferents, the magnesium ion is displaced and the NMDA receptor is activated. This sensitizes the second-order neurons that will then discharge at a higher frequency. When sensitization occurs, the firing threshold is reduced, so even slightly painful stimuli (hyperalgesia) and nonpainful stimuli (allodynia) cause sustained activation of the second-order neurons. NMDA receptor activation is linked to *windup* and *central sensitization* (ie, decreased thresholds for response or increased vigor of responses after a sensitizing event) and may contribute to the maintenance of chronic pain conditions with processes occurring both at the dorsal horn level and in the supraspinal areas. Central sensitization may occur with all types of pain when prolonged primary afferent activation causes *plasticity* (adaptation) of the pain sensory thresholds in the CNS.[11]

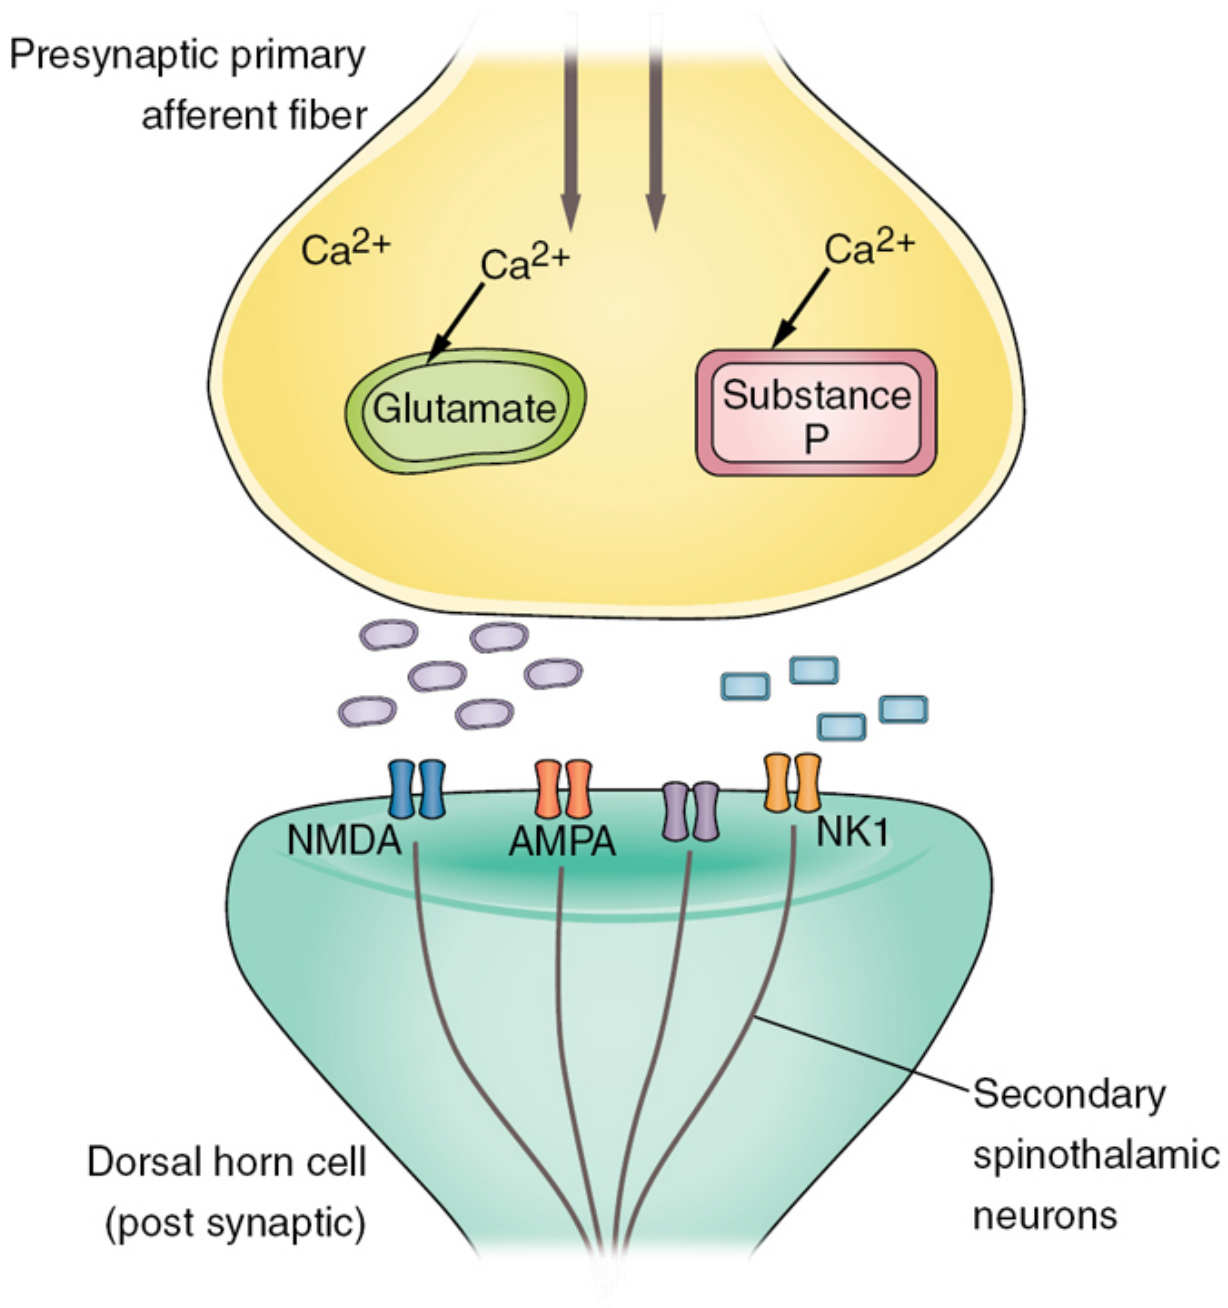

Figure 55-3 Synaptic activity at the dorsal horn. AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionate; NK1, neurokinin 1; NMDA, *N*-methyl-D-aspartate.

One of the predominant contributors to pain propagation at the synapse and in the CNS is the glial cell. In the periphery, these are Schwann cells and satellite cells. In the CNS, these include oligodendrocytes, astrocytes, ependymal cells, and microglia. Glial

cells account for 70% of the CNS, and under normal conditions, microglia account for 5% to 20% of glia.[12] The glial cells have historically been seen as support cells for synaptic homeostasis; however, they also have an important role in the synthesis, release, and uptake of neurotransmitters and serve as a link between the nervous system and the immune system. Nerve damage caused by trauma, infection, drugs, or toxins exposes peripheral nerve proteins, and they are seen by the immune system as “nonself,” initiating an immune reaction. Glial cells are activated, causing the release of cytokines and inflammatory mediators, thus contributing to peripheral sensitization, increasing nociceptor sensitivity, and lowering of the firing threshold. Continuous nociceptive input results in high levels of glutamate at the synapses. In the setting of chronic pain, glial cells swell (called *gliosis*), and an increase in cell-surface markers is seen. The more persistent the stimulus, the more they swell and release inflammatory mediators. This contributes to the development and maintenance of central sensitization. Glial cells and NMDA receptors may also be activated by medications, such as opioids. This is thought to contribute to opioid tolerance, dependence, addiction, and a phenomenon called *opioid-induced hyperalgesia* (OIH).[11,13]

Visceral pain is very complex. It follows somatosensory pathways and its own systems. Aδ and C fibers have been found in the heart, pleura, abdominal cavity, gallbladder, and testicles. In addition, the intestinal tract has its own neuronal system called the “brain–gut axis” that operates independently and in conjunction with the rest of the CNS.[14] Like the somatosensory pathways, peripheral and central sensitization occurs with chronic visceral pain. Activation of the autonomic nervous system may also affect visceral sensitivity and the role of emotions in modulating visceral pain. Visceral pain may be referred to areas of the somatosensory system (eg, myocardial ischemia causes left arm pain), leading to a complex presentation of pain.[7,14]

SUPRASPINAL MODULATION AND THE DESCENDING PATHWAY

Once nociceptive signals reach the CNS (typically at the spinal cord level), they ascend to the thalamus, primarily via the spinothalamic tract. From the thalamus, tertiary neurons project to many structures in the brain, including the brainstem, diencephalon (includes the thalamus), primary and secondary somatosensory cortices, and frontolimbic area. The somatosensory cortex is where the brain interprets the qualities of pain, such as location, duration, and intensity. Tertiary neurons also project to the limbic system, which is involved in the affective or emotional component of pain. *Perception* is when the sensory (physical) and affective (psychological) components of the nociceptive message are integrated into the patient's overall experience. An individual does not experience pain until the brain has processed and interpreted the electrical nociceptive signal.

A second tract, called the *spinoreticular* tract, not only ascends to the thalamus but also branches off at the brainstem to stimulate descending modulation. *Modulation* happens throughout the CNS and results in either an increase or a decrease in transmission. Neurons from the thalamus and brainstem release inhibitory neurotransmitters, such as norepinephrine (NE), serotonin (5-HT), γ-aminobutyric acid (GABA), glycine, endorphins, and enkephalins, which inhibit EAA activity in the ascending pathway. GABA is more active at the supraspinal sites, and glycine is more active at the spinal sites. The GABA-A receptor is a binding site for benzodiazepines and barbiturates, and the GABA-B receptor is a binding site for baclofen, causing muscle relaxation. Glycine has both pronociceptive and antinociceptive effects, depending on the receptor. Endogenous opioids (endorphins, enkephalins) are the most common group of inhibitory peptides, inhibiting EAA release from the presynaptic terminals and activation of the second-order neurons in the postsynaptic terminals. Opioids also enhance the descending pathway via the release of NE and 5-HT. In fact,

activation of most of the supraspinal structures results in enhancement of NE and 5-HT effects.

Diagnosis and Clinical Presentation

Pain is a symptom and a reactionary response to real or potential bodily harm, but it is not currently defined as a specific disease state. It also cannot be measured objectively. It is a symptom that relies on a patient's subjective report and any physical findings indicative of underlying pathology. Health care teams take on the task of identifying the cause of the pain using everything from noninvasive imaging such as magnetic resonance imaging to invasive testing such as electromyelograms and spinal discography.

Pain can be classified in many ways. Some conditions are classified as syndromes because the patient presents with a constellation of symptoms that cannot be attributed to any definitive diagnosis or disease process (eg, complex regional pain syndrome). Often, clinicians simply state the location and type of pain (eg, neuropathic pain in bilateral lower extremities). Cancer-related pain, whether from the disease process itself or the treatment of the disease (eg, surgery, chemotherapy, or radiation), presents very much like noncancer pain. One of the most common ways to classify pain is to describe the time course. *Acute pain* is caused by an injury or illness. It alerts an individual to the injury and initiates withdrawal from the noxious stimulus. It typically has an easily identified cause and location. The course is predictable, and the pain is expected to diminish in hours, days, or weeks as the injury heals. It may be associated with an inflammatory response, producing redness and swelling. Inadequately treated acute pain can evoke physiologic hormonal responses that alter circulation and tissue metabolism; these can also produce tachypnea, tachycardia, widening of the pulse pressure, and increased sympathetic nervous system activity. It can also cause emotional distress.

Chronic pain serves no biologic purpose. It is characterized by persistent pain that lasts beyond the length of an illness or the

healing of an injury. Sometimes, there is no apparent cause. It may be either continuous or recurrent and of sufficient duration and intensity to adversely affect a patient's well-being, level of function, and quality of life. Risk factors for developing chronic pain include individual predisposition (eg, female sex, increasing age, or a genetic predisposition), environmental factors (eg, previous painful experiences or abuse), and psychological factors (eg, anxiety, depression, or catastrophizing).[7]

Chronic pain can be further classified based on mechanism, symptoms, or location of injury. *Musculoskeletal* or *inflammatory pain* is described as constant, aching pain, often mediated by prostaglandins. It is usually caused by injury to the skeletal muscles or joints. Pain may be localized to the joints (as in rheumatoid arthritis and OA) or more regional (as with myofascial pain or muscle strain). *Neuropathic pain* is described as tingling, sharp, shooting, stabbing, burning, or other uncomfortable feelings (*dysesthesias*) such as the sensation that there are bugs crawling on the skin. Neuropathic pain may be constant (as in diabetic peripheral neuropathy [DPN]) or intermittent (as in trigeminal neuralgia). It is typically caused by injury in the nervous system or a nervous system response to persistent pain stimulus from outside the nervous system. *Visceral pain* can have a vague presentation, because the enteric and autonomic nervous systems are involved. Patients may report nausea or generalized abdominal discomfort (as in endometriosis, hepatitis, or pancreatitis). Some people report pain in the absence of physiologic tissue damage; however, their perception of the pain is very real. This is called *dysfunctional pain.* Conditions such as irritable bowel syndrome, fibromyalgia, interstitial cystitis, and some abdominal or pelvic pain fall into this category. In these conditions, pain appears to be generated by an imbalance in pronociceptive signals and antinociceptive signals in the CNS. Patients with dysfunctional pain syndromes are heavily influenced by factors that augment or diminish the CNS pathways, including stress, anxiety, depression, or illness.

Assessment

Pain is very subjective and difficult to measure in quantitative terms. It is essential to obtain a thorough history and examination, both physical and psychological. When obtaining a pain history, clinicians should gather details about the pattern, duration, location, and character of the pain and should additionally determine what makes the pain worse and what makes it better, what medications and nonpharmacologic therapies have been tried in the past, and the result of those therapies (positive or negative outcome) (**Table 55-1**).

Table 55-1
Patient Evaluation

General History
Chief reason History of present illness Past medical history Family history Social history (smoking, alcohol, illicit drugs) Current medications, including allergies or intolerances Sleep
Pain Assessment
Location Onset Duration Quality Intensity Ameliorating factors Exacerbating factors Pain rating, if possible
History of Nonpharmacologic Therapy
Interventional procedures Physical therapy Chiropractic Acupuncture TENS Aquatic therapy Yoga/Tai Chi

History of Pain Pharmacotherapy
Current and past analgesics Dose/route Duration of use Effectiveness Adverse effects
Clinical Examination
Clinician observations of patient behavior (grimacing, withdrawing, guarding) Physical examination Functional assessment

TENS, transcutaneous electrical nerve stimulation.

Pain intensity should be measured using an appropriate pain scale according to the patient's ability to communicate (**Table 55-2**, **Fig. 55-4**).[15] Single-dimensional pain scales tend to be more accurate in the acute pain setting and not as helpful for chronic pain because they only capture a "snapshot" of what the patient is feeling. Chronic pain symptoms wax and wane over time, so more useful tools are multidimensional pain scales that evaluate function, including sleep, appetite, performance of activities of daily living, work, and social interactions. Examples of multidimensional tools include the PEG (Pain intensity, Enjoyment of life, General activity) scale, McGill Pain Questionnaire, and the Brief Pain Inventory.[16–18] Ultimately, the most useful aspect of patient assessment is the information provided by the patient on how pain impacts day-to-day life, such as the number of hours they spend on their hobbies, or how well they can perform activities of daily living. Some of the most difficult patients to assess are young children and patients with cognitive, visual, or hearing impairment. These patients may have difficulty describing and communicating their pain and discomfort. There are multiple assessment tools that are designed and tested in these special populations to increase the accuracy of pain assessment. In addition to physical and functional assessments, psychological evaluations help to identify those patients who may need behavioral interventions to help them cope with their chronic pain. Because controlled substances may be used to treat chronic pain, screening

for substance use disorders is recommended (see Case 55-6, Question 4).[19]

Table 55-2
Pain Assessment Tools for Adults

Tool	Method of Administration	Advantages	Disadvantages
Visual analog scale (VAS)	Verbal, visual	Reliable; sensitive to acute changes in pain	Requires paper/pencil, mechanical skills; decreased reliability with cognitive, visual, or auditory impairment; not sensitive to long-term changes in pain
Numerical rating scales (NRS)	Verbal, visual	Reliable; good validity; detects treatment effects acutely	Decreased reliability with extremes of age; requires abstract thought, difficult to use with cognitive, visual, or auditory impairment; not sensitive to long-term changes in pain
Pain intensity [P], Enjoyment of life [E], General activity [G] (PEG)	Verbal, visual	Reliable; good validity; 3-item brief assessment; sensitive to long-term changes. Assesses function and values in addition to NRS	Does not provide specifics about reported pain. Does not assess quality of pain or affective component. Difficult to use with cognitive, visual, or auditory impairment
Verbal description scales (VDS)	Verbal, visual (4- or 5-point scales)	Reliable; good validity; preferred by older adults; preferred by some over NRS or VAS	Dependent on literacy and language; limited number of response categories, unequal intervals between anchors; not very sensitive to changes in pain
Faces pain scale	Visual	Reliable; good validity; good with poor literacy or language barrier; possibly easier than NRS or VDS	Requires abstract thinking; not specific for pain
Brief pain inventory (BPI)	Verbal, written	Reliable; intensity and interference components; sensitive to change in condition over time	Does not assess quality of pain or affective component
McGill Pain Questionnaire (MPQ)	Verbal, written (long form—30 minutes; short form—2–3 minutes)	Reliable; measures sensory and affective components; valid in older patients	Not recommended for illiterate or cognitively impaired patients

Services [CMS], an Agency of the U.S. Department of Health and Human Services.)

Overview of Treatment

Treatment of pain is based on guidelines whenever possible. However, the number of treatment guidelines for pain management is limited. More commonly, clinicians choose a therapy based on the type of pain (eg, neuropathic, musculoskeletal, inflammatory, visceral, and central). For all types of pain, multimodal therapy including pharmacologic, physical rehabilitation, and behavioral interventions should be combined. Interventional therapies should be considered if possible.

A treatment plan must always include evaluation of the following factors: age, comorbidities (such as renal and liver disease), route of administration (the oral route may not be suitable), concurrent medications (for duplication or drug–drug interactions), laboratory abnormalities, and financial resources.

Acute pain is usually managed very effectively with nonsteroidal anti-inflammatory drugs (NSAIDs), acetaminophen, and/or opioids, but may include adjunctive therapies as well. Pharmacotherapy for chronic pain is more complex. The first-line agents for the treatment of neuropathic pain consist of antidepressants, preferably serotonin-norepinephrine reuptake inhibitors (SNRIs) or tricyclic antidepressants (TCAs). These agents enhance the descending inhibitory pain pathway. Anticonvulsants (eg, sodium-channel blockers, calcium-channel blockers, or GABA agonists) are also considered the first-line therapy for many common types of neuropathic pain. They inhibit activation of sodium and calcium channels, block release of EAAs such as glutamate, or block the postsynaptic receptors. Some anticonvulsants also enhance the inhibitory effects of GABA. If the pain is localized, topical agents may be useful (eg, capsaicin or lidocaine). Addition of an opioid may be considered if the former agents fail to provide adequate analgesia. Combination therapy has been shown to be more effective in some

cases (TCA–anticonvulsant or opioid–anticonvulsant combinations).[20] Nerve blocks and other interventional therapies may be helpful for short-term relief.[21]

Chronic musculoskeletal pain usually responds to acetaminophen, salicylates, or NSAIDs, in addition to nonpharmacologic therapies such as heat and ice or physical rehabilitation modalities. Localized pain may be amenable to topical therapies (NSAIDs, capsaicin), and trigger points (ie, taut muscle bands) may be amenable to injections. SNRIs may also be considered for this indication.[22]

Visceral pain is complex, and there are no clear treatment guidelines. Because it travels the somatosensory pathways, antidepressants that enhance inhibitory modulation are most commonly used. In addition, anticonvulsants that reduce central sensitization and hyperalgesia may be helpful.[23]

Trials of any pharmacologic therapy must be monitored for both efficacy and toxicity. Patients must have realistic expectations for any medication trial. Even the most effective analgesics are expected to achieve only about 30% to 50% improvement in chronic pain. This is why multimodal therapy is essential. NSAID therapy should be accompanied by monitoring for dyspepsia, peptic ulcers, gastrointestinal (GI) bleeding, elevated blood pressure, and declining renal function, at a minimum. Antidepressants do not usually require laboratory monitoring but are known to cause dry mouth, constipation, urinary retention, and drowsiness. Some of the anticonvulsants require laboratory monitoring for liver toxicity, electrolyte imbalance, or bone marrow abnormalities. All anticonvulsants may cause drowsiness, dizziness, and cognitive dysfunction, with short-term memory loss and word-finding difficulty. Opioids require laboratory monitoring for long-term adverse effects, such as osteoporosis, hypogonadism, and end-organ impairment, and patients must be routinely screened for sleep apnea, constipation, drowsiness, nausea, and vomiting. Drug interactions, both pharmacokinetic (eg, hepatic enzyme interactions) and pharmacodynamic (eg, additive sedation), are common with many of these agents, particularly when used in combination.

Perioperative Pain Management

More than 80% of surgical patients experience postoperative pain, and of those patients, up to 40% experience “severe” pain.[2,3] The mismanagement of postoperative pain, whether undertreatment or overtreatment, is associated with negative physiologic consequences, such as persistent postoperative pain, impaired rehabilitation, increased hospital length of stay, and adverse events related to excessive analgesic use. Multimodal treatment must be utilized throughout the perioperative continuum to effectively manage pain.

Pain management during the perioperative period can be divided into three phases: preoperative, intraoperative, and postoperative analgesia. Preoperative analgesia is treatment started 1 to 2 hours before surgery, with medications used to decrease peripheral sensitization. Intraoperative analgesia prevents the establishment of central sensitization caused by incisional injury and includes only the procedure time period. Postoperative analgesia is aimed at proactively reducing acute pain and preventing central sensitization, thereby avoiding subsequent development of chronic pain.[11]

Normally, the acute pain trajectory has a rapid decline during the first week after surgery, and most patients fully recover within a few weeks with no residual pain.[24] For 10% to 13% of patients, pain intensity will remain high throughout the postoperative course and persist for several months.[25] Although there is no single definition of a time frame for chronic pain, chronic postsurgical pain (CPP) is pain that occurs at the site of the incision or related areas of the surgery and continues beyond the time frame that it takes for most injured tissues to fully heal. The time of CPP onset is between 3 and 6 months.[26,27]

The prevalence of CPP is highest with limb amputation, thoracotomy, mastectomy, hernia repair, and cardiac surgery (**Table 55-3**).[11,27] Risk factors for CPP include history of chronic pain before surgery, gender, age, surgical site, invasiveness of surgery, unrelieved postoperative pain, and comorbid anxiety or depression.[26]

Genetic factors also account for a significant degree of interindividual variation in pain sensitivity and treatment response.[11,26]

Table 55-3
Prevalence of Chronic Postsurgical Pain

Type of Surgery	Incidence of Chronic Pain (%)	Clinical Presentation
Limb amputation	30–85	Phantom limb pain
Mastectomy	20–50	Scar pain, phantom breast pain, shoulder or arm pain, chest wall pain
Thoracotomy	60–75	Scar pain, chest wall pain
Coronary artery bypass surgery	30–50	Sternal pain, postsaphenectomy pain
Inguinal hernia repair	5–55	Scar pain, ilioinguinal nerve pain, inflammatory pain

Postoperative pain management and opioids: transition from acute to chronic pain after surgery. *Lancet*. 2019;393:1537–1546.

CASE 55-1

Question 1: B.B. is a 46-year-old female who sustained a shoulder injury while pulling a cart at work. She will be undergoing total shoulder arthroplasty in 2 weeks. She also has fibromyalgia and takes hydrocodone/acetaminophen 5 mg/325 mg with one to two tablets by mouth every 6 hours (usually takes eight tablets daily) as well as duloxetine 30 mg by mouth daily and pregabalin 75 mg by mouth twice daily. She smokes one pack of cigarettes daily and has "a few" glasses of wine nightly to help her pain because she does not think her current analgesic regimen is effective.

What assessment should be done with B.B. before surgery? What risk factors does she have for increased pain after surgery?

It is paramount that all patients have a thorough preoperative assessment, including review of medical comorbidities, medications, history of chronic pain, and substance abuse, as well as prior postoperative analgesic regimens and responses.[28] Pharmacists

should also ask about sleep-disordered breathing (SDB) because some patients may experience sleep apnea but are unaware of the condition. The presence of central sleep apnea or obstructive sleep apnea (OSA) is associated with a higher risk for perioperative complications. Preexisting SDB, often rated as moderate to severe, is present in 70% to 85% of patients taking long-term opioids.[29] Central sleep apnea is repetitive cessation or decrease of both airflow and ventilatory effort during sleep and is more predominant than OSA.[30] A screening tool called STOP-BANG can be utilized to assess for sleep apnea risk (**Table 55-4**).[31]

Table 55-4
Stop-Bang Questionnaire

Do you snore loudly?
Do you feel tired, fatigued, sleepy during the day?
Has anyone observed you stop breathing during sleep?
Are you being treated for high blood pressure?
BMI >35 kg/m^2
Age >50 years
Neck circumference >40 cm
Male gender
Yes to ≥3 items = high risk for OSA
Yes to <3 items = low risk of OSA

BMI, body mass index; OSA, obstructive sleep apnea.

As part of a preoperative medication assessment, pharmacists need to review medications that the patient takes at home and develop a plan to resume them after surgery. Laboratory data for renal, liver, and pulmonary function need to be reviewed to determine whether medication dose adjustment may be needed before surgery. For patients taking opioids before surgery, pharmacists should obtain prescribing data from their respective

state prescription drug monitoring program (PDMP) to determine what controlled substances the patient has been filling and ask the patient how each medication has been taken at home. Current and past substance use should be addressed in an open and nonjudgmental manner.[32]

Patients always bring their past experiences and current fears to surgery. These factors affect how they perceive and cope with acute pain after surgery (**Table 55-5**).[26] Risk factors for increased pain after surgery in B.B. include female gender, work injury, and chronic opioid therapy.[26] Functional pain syndromes (FPSs) such as fibromyalgia are associated with inefficient diffuse noxious inhibitory control (DNIC). This means that the inhibitory pathway is not effectively blocking pain transmission into the CNS, and she will likely have an exaggerated pain response to surgery. Her chronic opioid use could also complicate pain management because she will likely require higher opioid doses after surgery.[32]

Table 55-5
Risk Factors for Increased Postoperative Pain

Adverse experience with previous surgery
Preexisting pain (moderate-severe >1 month)
Psychological vulnerability
Younger age
Female
Workers' compensation
Inefficient diffuse noxious inhibitory control (DNIC)
Genetic predisposition
Use of chronic opioid therapy

Case 55-1, Question 2: What should be done to help B.B. prepare for surgery?

Clinicians should provide the patient and family with individually tailored education, including information on treatment options for the management of postoperative pain, making sure to document the plan and goals in the medical record and on paper for the patient to take home.[28] Patient-tailored education has been shown to reduce postoperative opioid consumption, preoperative anxiety, requests for sedatives, and length of stay.[28,33] Education should include changes in analgesics before surgery, reporting and assessment of pain and when to report, multimodal pharmacologic and nonpharmacologic options, as well as realistic goals for pain control.[32]

For B.B., there needs to be education about her substance use. Many surgeons require patients to stop smoking before surgery to improve healing (for smoking cessation strategies, see Chapter 91, Tobacco Use and Dependence). Given her regular intake of alcohol, tapering off this before surgery is important, because she may develop alcohol withdrawal after surgery if she continues to consume alcohol. This complicates postoperative care and prevents the use of valuable analgesics such as acetaminophen because of additive liver toxicity. Because she is getting little to no benefit from her opioid, it is recommended to discontinue hydrocodone/acetaminophen via taper over the next 2 weeks to reduce her tolerance and improve her postoperative response to opioid analgesics.[32] Some time also needs to be devoted to reducing her anxiety and educating her that she may have an exaggerated pain response. Increasing the dose of pregabalin may help with this as part of a multimodal analgesic regimen, and duloxetine could be continued.

Case 55-1, Question 3: Based on current guidelines, what anesthesia modalities may be part of a multimodal pain management approach for B.B.?

A multimodal approach to surgical pain management may include a combination of nonpharmacologic therapies, nonopioid medications, systemic analgesics, and nerve blockade through regional or neuraxial anesthesia.[34] It is important to note that there

are many different nerve blocks for the body trunk and extremities. The choice of nerve block depends on the type of surgery, location of the block, medication, and risk for complications. *Neuraxial anesthesia* is a term associated with the epidural or intrathecal route of administration. An intrathecal spinal injection is a single dose of either an opioid and/or local anesthetic administered into the cerebrospinal fluid (CSF) in the subarachnoid space near the region where pharmacologic effect in the spinal cord is needed.[35]

Intrathecal medication doses are significantly lower compared to epidural owing to the direct injection into the CSF. Analgesia with an intrathecal single injection will wear off according to the half-life of the medication used (**Table 55-6**).[36] Some anesthesiologists use a small amount of epinephrine to cause local vasoconstriction and keep the medication from dispersing rapidly through the CSF.[37] Common complications with intrathecal injections include postdural puncture headaches (ie, CSF can leak after puncture of the subarachnoid dura) and itching with opioids. More serious complications include delayed respiratory depression (with opioids), hypotension (with local anesthetics), infection, and intraspinal hematomas.

Table 55-6
Injectable Local Anesthetics

Pharmacodynamics/Kinetics								
Injectable Local Anesthetics: Pharmacokinetics								
	Distribution	**Protein Binding**	**Onset of Action**	**Time to Peak**	**Duration of Action**	**Metabolism**	**Half-life Elimination**	**Excretion**
Bupivacaine hydrochloride	Children: 2.7 ± 0.2 L/kg Infants: 3.9 ± 2 L/kg	84%–95%	Anesthesia (route and dose dependent): ■ Epidural: ≤17 minutes to spread to T6 dermatome ■ Dental injection: 2–10 minutes ■ Infiltration: Fast ■ Spinal: Within 1 minute; maximum dermatome level achieved within 15 minutes in most cases	Caudal, epidural, or peripheral nerve block 30–45 minutes	Route and dose dependent: ■ Epidural: 2–7.7 hours ■ Infiltration: 2–8 hours ■ Dental injection: ≤7 hours ■ Spinal: 1.5–2.5 hours	Hepatic; forms metabolite (pipecoloxylidine [PPX])	Age dependent: ■ Adults: 2.7 hours ■ Neonates: 8.1 hours	Urine (~6% unchanged)
Bupivacaine liposomal		95%	Rapid	Within 1 hour (initial peak); 12–36 hours (second peak)	Local: ≤72 hours Systemic: Plasma levels can persist for 96 hours after local administration and 120 hours after interscalene brachial plexus nerve block	Hepatic via conjugation; major metabolite PPX (inactive)	13–34 hours	Urine (~6% unchanged)
Chloroprocaine	Depends upon route of administration; high concentrations found in highly perfused organs such as the liver, lungs, heart, and brain		6–12 minutes		Up to 60 minutes (patient, type of block, concentration, and method of anesthesia dependent)	Rapidly hydrolyzed by plasma enzymes to 2-chloro-4-aminobenzoic acid and β-diethylaminoethanol (80% conjugated before elimination)	In vitro. plasma: ■ Adults: 21 ± 2 seconds (males). 25 ± 1 seconds (females) ■ Neonates: 43 ± 2 seconds	Urine (minimal as unchanged drug in urine; metabolites: Chloroaminobenzoic acid and β-diethylaminoethanol primary excreted unchanged)
Lidocaine	1.5 ± 0.6 L/kg; range: 0.7–2.7 L/kg; alterable by many patient factors; decreased in CHF and liver disease; crosses blood–brain barrier	60%–80% to α-1 acid glycoprotein	Single bolus dose: 45–90 seconds		10–20 minutes	90% hepatic; active metabolites monoethylglycinexylidide (MEGX) and glycinexylidide (GX) can accumulate and may cause CNS toxicity	Biphasic: ■ Initial: 7–30 minutes ■ Terminal: ■ Adults: 1.5–2 hours ■ Infants, premature: 3.2 hours	Urine (<10% as unchanged drug. ~90% as metabolites)
Mepivacaine		~75%	Route and dose dependent: Range: 3–20 minutes; dental: upper jaw: 30–120 seconds; lower jaw: 1–4 minutes		Route and dose dependent: 2–2.5 hours; dental: upper jaw: 20 minutes; lower jaw: 40 minutes	Primarily hepatic via *N*-demethylation, hydroxylation, and glucuronidation	Adults: 1.9–3.2 hours Neonates: 8.7–9 hours	Urine (90%–95% as metabolites)
Prilocaine	190–260 L; crosses blood–brain barrier	40%–55% (α-1 acid glycoprotein)	Infiltration: <2 minutes Inferior alveolar nerve block: <3 minutes		Infiltration: Complete anesthesia for procedures lasting 20 minutes Inferior alveolar nerve block: ~2.5 hours	Primarily metabolized hepatically and to a lesser renally; prilocaine hydrolyzed by amidases to produce ortho-toluidine and *N*-propylalanine; these compounds may also undergo ring hydroxylation	1.6 hours	Urine (~5% as unchanged drug)
Ropivacaine	Vdc ■ Adults: Intravascular infusion: 41 ± 7 L ■ Children: Epidural infusion: 2.1–4.2 L/kg		Anesthesia (route dependent): 3–15 minutes	Dose and route depended: Caudal: ■ Children: Mean: 60 minutes (range: 12–249 minutes) ■ Infants: Median: 60 minutes (range: 15–90 minutes)	Dose and route dependent: 3–15 hours	Hepatic. Via CYP1A2 to metabolites	Adults: ■ Epidural: 5–7 hours ■ Children: ■ Epidural: Terminal phase: 4.9 hours (range: 3–6.7 hours)	Urine (86% as metabolites)
Tetracaine					1.5–3 hours	Hepatic: Detoxified by plasma esterases to aminobenzoic acid		Urine

Epidural analgesia is a pain management option for invasive abdominal surgical procedures and labor pain. The epidural space is the outmost region of the spinal canal that contains fat, epidural veins, spinal nerve roots, and connective tissue. Medication selection, concentration, and delivery mode (eg, continuous infusion, patient-controlled epidural dose) depend on the clinical indication. Morphine and hydromorphone are commonly used for surgical epidural administration in combination with a local anesthetic, such as bupivacaine or ropivacaine. Both morphine and hydromorphone are more hydrophilic compared to fentanyl, so it is difficult for them to pass through the lipophilic arachnoid meninges for penetration in the CSF once injected into the epidural space. Fentanyl is highly lipophilic and easily passes through membranes into the systemic circulation and CSF. Typically, fentanyl is combined with a local anesthetic for obstetrical labor. All epidural opioids travel cephalad to the brain via the CSF and may cause central respiratory depression. Epidural opioids also cause typical class-related adverse effects, such as itching and nausea, and cognitive effects, such as sedation or confusion, although these are centrally mediated.[38]

Local anesthetics must be monitored not only for pain coverage but also for toxicity. They most commonly cause hypotension, because sympathetic nerves are small. The more cephalad the epidural catheter tip is placed, the more likely that the sympathetic nerves serving the lungs, diaphragm, and heart will be affected. Local anesthetic systemic toxicity (LAST) can be life-threatening, causing seizures and cardiac dysrhythmias. The treatment of LAST involves rapid administration of intralipid, which will bind the local anesthetic.[39]

Regional anesthesia is commonly used for surgical procedures involving the upper trunk (chest and shoulders), upper extremities (arms and hands), and lower extremities (hip and legs).[40] Nerve blockade results from infiltration of local anesthetic around one or

more peripheral nerves to cause temporary loss of sensation in an area of the body.[41] Local anesthetics are highly lipophilic and diffuse across the plasma membrane to reversibly block voltage-gated sodium channels on the peripheral nerves. The sodium channel block interrupts the action potential and influx of sodium ions, thereby decreasing the sensory nerve conduction.[42] Advantages to peripheral nerve blockade include avoidance of general anesthesia, better management of the surgical stress response, reduction in postoperative opioid requirements, and quicker recovery from surgery.[43] The choice of local anesthetic in peripheral nerve blockade is mainly determined by desired speed of onset, block intensity, and duration of anesthesia. Plain bupivacaine or liposomal bupivacaine is more frequently used for single-injection peripheral nerve blocks.[44] Ropivacaine has largely replaced bupivacaine as the most commonly used long-acting (LA) local anesthetic in continuous peripheral nerve blocks (Table 55-6).[36] In equivalent doses, ropivacaine produces less motor blockade compared to bupivacaine but an equally effective sensory block.

The major limitation to a single-injection block is that the local anesthetic will only last a few hours. A single injection is best suited for surgical procedures in which postoperative pain is not expected to exceed 12 to 24 hours in duration; otherwise, patients are at risk for significant rebound pain.[34] Administration of local anesthetics via continuous infusion allows for a duration of analgesia significantly longer than that of a single injection. Continuous peripheral nerve blockade involves placement of an indwelling catheter in the perineural space (eg, around the peripheral nerves). The local anesthetic infusion can be delivered until the postoperative pain has subsided. The catheter may be connected to a hospital infusion pump or portable elastomeric pump for discharge to home with the patient. When comparing single-injection peripheral nerve blocks to continuous peripheral nerve blocks, continuous techniques tend to be associated with improved postoperative analgesia, improved patient satisfaction, and decreased total opioid consumption for certain surgeries.[45] The most commonly cited risks associated with peripheral nerve blocks include nerve injury, bleeding, infection,

intravascular injection, systemic local anesthetic toxicity, and injury to surrounding anatomic structures.[46]

For B.B., the anesthesia team will use regional anesthesia with an interscalene brachial plexus nerve block (ISB). The ISB is increasing in popularity with use in ~42% of patients undergoing shoulder arthroplasty in the United States.[47] Because shoulder surgery is so painful and recovery is long, B.B. will be discharged to home with a continuous infusion of ropivacaine for pain relief up to 7 days. Home care services will follow B.B. to assess the postoperative recovery and discontinue the ropivacaine infusion pump. B.B. will have her arm in a sling because her arm and hand will be numb and not functional while the nerve block is running. This form of longer term acute analgesia has been shown to reduce length of hospital stay and provide excellent pain relief.[48]

Multimodal Pain Management

CASE 55-2

Question 1: D.K. is a 35-year-old male admitted for a spine surgery. His past medical history is significant for lumbar spinal stenosis, resulting in foraminal compression of the spinal canal. Conservative therapies have failed to reduce the severity of the low back pain. Before admission for the surgery, the patient's medical history included:

Medical conditions:

Morbid obesity: height 70.86 inches (180 cm), weight 376.99 pounds (171 kg), body mass index (BMI) 51.5 kg/m^2

Type 2 diabetes, noninsulin dependent
Sleep apnea, uses continuous positive airway pressure (CPAP) at home
Degenerative joint disease of the lumbar spine
Hypertension
Medications:
Glimepiride 8 mg orally once daily
Lisinopril 20 mg orally once daily
Ibuprofen 600 mg orally once or twice daily for pain
Oxycodone/acetaminophen 5 mg/325 mg, one tablet every 4 hours as needed (prn) (reports taking four tablets every day)
Docusate/senna 100 mg/17.2 mg, two tablets orally at bedtime prn

In the postoperative anesthesia care unit (PACU), morphine 2 to 4 mg intravenous (IV) every 5 minutes is ordered for severe pain. D.K. received 8 mg of IV morphine over 30 minutes, then became very drowsy but is still reporting severe pain. The nurse is concerned about the level of sedation and does not want to give additional morphine.

Is morphine an appropriate opioid for postoperative pain control in D.K.?

After surgery is completed in the operating room, patients are transferred to the PACU for stabilization of respiratory function and pain. Most patients emerging from general anesthesia are still quite sedated when they are transferred to the PACU. When the anesthetic agents begin to wear off, it is very important to achieve rapid control of severe pain, so frequent administration of small IV opioid doses is common practice in this setting. Currently, there is not a universally accepted standard for titration of IV opioids in the PACU. Some institutions will allow the use of both IV fentanyl to gain fast pain control and morphine for a longer duration of action. Hydromorphone is an acceptable alternative to morphine for patients with renal insufficiency or intolerable side effects to morphine.

Morphine is considered the standard for IV opioid administration. The hydrophilic property of morphine delays penetration across the blood–brain barrier, so the relative time to onset is ~6 minutes after an IV dose. The concentration peak effect after an IV morphine dose is 20 minutes.[49] Major morphine metabolites include morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G).[50] The M3G metabolite is inactive, but M6G crosses the blood–brain barrier and has potent analgesic activity. Therefore, the analgesic and ventilatory depressant effects of morphine and M6G may not be evident with initial high plasma morphine concentrations.[51] Adverse events may occur 40 to 60 minutes after the last IV morphine dose.[51] Patients with renal insufficiency will have M6G metabolite accumulation and be at increased risk for respiratory depression, so morphine use is not recommended in this population.[52]

Hydromorphone is a semisynthetic hydrogenated ketone analog of morphine with 10 times higher lipid solubility compared to morphine, which contributes to its rapid CNS effects.[53,54] In comparison to morphine, the potency of hydromorphone is approximately seven

times higher for the IV route and four times higher than the oral route.[54–56] The concentration peak effect after IV hydromorphone administration is between 8 and 20 minutes.[57,58] Hydromorphone is predominately metabolized through the phase II glucuronidation pathway similar to morphine producing hydromorphone-3-glucuronide (H3G) and hydromorphone-6-glucuronide (H6G). The primary metabolite, H6G, lacks analgesic activity and has not been found to contribute significantly to side effects, thus making hydromorphone the preferred opioid over morphine. H3G metabolite production is significantly less than H6G, but H3G has been shown to accumulate in animal models, leading to dose-dependent myoclonus.[54,58] In patients with renal failure, the H3G metabolite may increase side effects, including nausea, delirium, and seizures.[54,59] Therefore, low initial dosing of hydromorphone is recommended in patients with renal failure.

Fentanyl is a synthetic phenylpiperidine compound with high lipid solubility, resulting in rapid transfer across the blood–brain barrier. Compared to morphine, fentanyl is 100 to 300 times more potent owing to optimization of the molecular configuration.[60] Fentanyl is almost completely metabolized in the liver by cytochrome P450 3A4 (CYP3A4), rendering the oral route ineffective because of the first-pass effect. For acute pain, the IV route of administration is recommended owing to the rapid onset of action. Analgesic effects occur within 1 to 2 minutes after IV bolus administration and last for ~30 minutes.[61] Caution with IV bolus dosing is needed because of the risk of chest wall rigidity resulting in respiratory failure. Chest wall rigidity is related to the dose and speed of delivery that has occasionally been encountered with a 50-μg dose.[61] After an IV dose, fentanyl redistributes into muscle and adipose tissue. Removal of fentanyl from muscle and adipose tissue is slower than uptake, because both tissues act as storage sites; in muscle, this is because of its mass, and in adipose tissue, this is because of the high lipid solubility of fentanyl. After initial equilibration, the adipose tissue slowly releases fentanyl back into the plasma, resulting in a lengthy elimination half-time of 3.1 to 7.9 hours.[60] Multiple, frequent fentanyl bolus dosing will lead to accumulation as a result of its long half-

time. Fentanyl is a good option for rapid pain control during surgical procedures in the operating room, but is not the best choice for postoperative pain control in obese patients.[62]

For the management of D.K.'s pain in the PACU, the morphine order should be changed to IV hydromorphone 0.2 to 0.4 mg every 10 minutes for severe pain. Hydromorphone does not have appreciable H6G metabolite accumulation and does not distribute into adipose tissue. After D.K.'s pain is stabilized in the PACU, the interval will need to be longer between doses owing to the declining acute pain trajectory and addition of other multimodal medications that will decrease the opioid requirements. In addition to pain management, it is very important to anticipate postoperative nausea and vomiting (PONV) caused by anesthetic agents and opioids. Antiemetics are commonly used for the prevention of severe PONV (refer to Chapter 22 for management of PONV).

CASE 55-2, QUESTION 2: Is D.K. an appropriate candidate for IV patient-controlled analgesia (PCA)?

For postoperative pain management after discharge from the PACU, the oral route is preferred to IV administration unless the patient is unable to take oral medication or has severe uncontrolled pain.[28] The use of PCA provides a precise and convenient method for IV opioid administration that allows the patient to activate the dose for acute pain management. The IV PCA route is preferred to nurse-administered IV doses because the patient does not have to notify the nurse when more medication is needed, wait until it is given, and then further wait for the peak effect to occur for pain relief. Self-administration of smaller and more frequent IV opioid doses reduces the variation between the peak and trough effect of the dosing interval, thus providing better maintenance of the plasma opioid concentration.[63]

Patients who are appropriate for PCA must be able to cognitively understand how to use a dose button for opioid self-administration and who will require IV opioid for many hours.[28] The PCA dose

button is connected to an infusion pump that will allow the administration of an opioid dose when the button is pushed (ie, demand). To prevent overdosage by continual demand, all PCA devices use a lockout interval, which is the length of time after a successful patient demand during which the device will not administer another dose even if the patient pushes the button.[63] Most patients who start IV PCA are opioid naïve, meaning that their opioid use the week before surgery was <60 mg[64,65] of oral morphine or its equivalent.[64] For this reason, the starting dose for IV PCA is standardized for opioid-naïve patients (**Table 55-7**).[65]

Table 55-7

Patient-Controlled Analgesia

Dosing Parameter	Fentanyl 10 µg/mL	Hydromorphone 0.2 mg/mL	Morphine 1 mg/mL
Maximum dose	The total amount of drug over time and the maximum number of patient demand doses per hour will vary.	The total amount of drug over time and the maximum number of patient demand doses per hour will vary.	The total amount of drug over time and the maximum number of patient demand doses per hour will vary.
Loading dose	20 µg bolus	0.4 mg (400 µg) bolus	2 mg bolus
Clinician dose	20 µg bolus. One clinician bolus may be given each hour.	0.4 mg (400 µg) bolus. One clinician bolus may be given each hour.	2 mg bolus. One clinician bolus may be given each hour.
PCA dose	10 µg with a lockout time of 10 minutes	0.2 mg (200 µg) with a lockout time of 10 minutes	1 mg with a lockout time of 10 minutes
Basal dose	Not recommended for starting PCA		

PCA: patient-controlled analgesia.

The use of a continuous opioid infusion for postoperative pain management is generally reserved for patients who are opioid tolerant. The role of the continuous infusion is to provide a steady baseline of opioid medication that mimics the dose taken before surgery. The use of IV PCA along with a continuous infusion in opioid-tolerant patients can help optimize pain control.

In this case, PCA therapy without a continuous infusion would be appropriate for D.K. based on the invasive surgery and anticipated severe postoperative pain. Before admission, D.K. reported taking 20 mg of oxycodone daily. Using the equianalgesic conversion table (**Table 55-8**), 20 mg of oral oxycodone is equivalent to 30 mg of oral morphine.[55,56] Therefore, D.K. is opioid naïve based on total daily

use of oxycodone being equivalent to <60 mg of oral morphine. Hydromorphone 0.2 mg IV with a lockout interval of 10 minutes is recommended because D.K. is at high risk for respiratory depression as he is opioid naïve, morbidly obese, and has a history of sleep apnea.[53] Because D.K. is experiencing sedation because of morphine administration in the PACU, the PCA dose should be started after he is more alert. Nonopioid analgesic medications that are not sedating should be used to provide synergistic pain management and can be used throughout the postoperative period.

Table 55-8
Opioid Conversion Calculations

Drug	Equianalgesic Dose Calculation[a]		Oral Morphine Milligram Equivalent[b]
	Use for conversion between intravenous (IV) and oral opioid		Conversion factor for oral opioid prescription data calculations. Do not use for IV conversions.
	Oral	IV	
Fentanyl	Not available	0.1 mg	0.13 (buccal or sublingual)
Hydrocodone	30 mg	Not available	1
Hydromorphone	7.5 mg	1.5 mg	4
Morphine	30 mg	10 mg	1
Oxycodone	20 mg	Not available	1.5
Oxymorphone	10 mg	1 mg	3

[a]See below for example of equianalgesic dose calculation.

[b]See below for example of calculation using oral morphine milligram equivalent (MME).

Calculation Example 1: **Equianalgesic conversion from oxycodone 5 mg to morphine IV.**

Step 1: Select the equianalgesic dose ratio that corresponds to the opioid and route that will be converted from the table above. Ratio calculations should be set up to correlate the actual dose with the equianalgesic equivalent as shown below:

"X" mg total daily dose of new opioid = equianalgesic factor of new opioid

<60 mg total daily dose of current opioid = equianalgesic factor of current opioid

Step 2: For the conversion, 20 mg of oral oxycodone is equianalgesic to 10 mg IV morphine.

"X" mg total daily dose of new opioid = 10 mg IV morphine

5 mg oral oxycodone = 20 mg oral oxycodone

Step 3: Cross multiply the ratio to determine the total daily dose of IV morphine.

(20)(X) = (10)(5)

20X = 50

X = 2.5 mg of IV morphine

When switching to a new opioid, the initial daily dose for the new opioid should be reduced by 25% to 50% to adjust for incomplete μ-receptor cross-tolerance.

Calculation Example 2: Calculate the daily MME for an acute pain discharge prescription of oxycodone 5 mg oral every 4 hours prn.

Step 1: Determine the maximum units per day of tablets that could be taken.

(1 oxycodone 5 mg tablet) (6 per day) = 6 tablets per day

Step 2: Determine the MME per day

Tablet strength × units per day × MME factor = MME per day

(5 mg) (6 per day) (1.5) = 45 MME per day

Data from Facts & Comparisons eAnswers. Accessed September 23, 2022. https://fco.factsandcomparisons.com/lco/action/home; National Center for Injury Prevention and Control. CDC compilation of benzodiazepines, muscle relaxants, stimulants, zolpidem, and opioid analgesics with oral morphine milligram equivalent conversion factors, 2016 version. Centers for Disease Control and Prevention; 2016. https://www.cdc.gov/drugoverdose/media/

Case 55-2, Question 3: What are potential risk factors for respiratory depression related to opioid therapy that need to be considered for D.K.?

Respiratory depression remains the most serious adverse event related to opioid therapy, often because of excessive amounts or frequent use of an opioid beyond what is needed to achieve pain control. There are many factors that increase the risk of opioid-induced respiratory depression with IV and oral therapy related to comorbid medical conditions. Patients with advanced age older than 65 years, renal insufficiency, history of sleep apnea, or morbid obesity are at higher risk for developing opioid-induced respiratory depression. Morbid obesity is defined as a BMI >40 kg/m^2 and presents a significant challenge for perioperative acute pain management. Patients with morbid obesity have a higher risk of respiratory depression related to OSA and altered medication clearance due physiologic changes in organ systems, including renal and liver.[62]

To prevent respiratory depression in high-risk patients, the lowest possible starting dose of an opioid should be initiated, and the use of a continuous infusion should be avoided. For all patients, avoid administration of more than one drug with sedating properties at the same time with opioids.[28] Medications including antihistamines, benzodiazepines, gabapentin, pregabalin, and skeletal muscle relaxants should be scheduled ~2 hours apart to prevent accumulation of sedating side effects.

Case 55-2, Question 4: How is naloxone administered for reversal of respiratory depression?

For hospitalized patients who experience excessive sedation and cannot be aroused with sternal stimulation, or have a significant decline in breathing, naloxone administration may be needed to reverse the opioid CNS effects. Naloxone is a nonselective competitive opioid antagonist of all pharmacologic effects on μ, δ, and κ receptors. After oral administration, naloxone is extensively metabolized in the liver (ie, >95% first-pass effect), rendering it ineffective; therefore, IV, intramuscular, or subcutaneous administration at an initial dose of 0.4 mg is required for reversal of life-threatening respiratory depression.[66] The extent and duration of naloxone reversal of opioid-induced respiratory effects is highly variable and is related to many factors, including the specific opioid used, the opioid dose, administration mode, concurrent medication, underlying disease, and pain. Therefore, naloxone administration may need to be repeated every 2 to 3 minutes or given as a continuous infusion until full recovery of respiratory function.[67]

Case 55-2, Question 5: How can opioid-induced constipation be prevented?

Owing to the distribution of μ-opioid receptors in the enteric nervous system, common side effects of opioid therapy include constipation, decreased appetite, increased reflux, nausea, and vomiting. An abundance of literature and guidelines exist endorsing

the use of stool softeners, osmotic agents, and stimulant laxatives for the prevention of opioid-induced constipation with acute pain management.[28] However, there are many shortcomings to laxative use with chronic opioid therapy. Peripherally acting μ-opioid receptor antagonists such as methylnaltrexone or naloxegol bind to receptors in the enteric nervous system and may be needed to restore functional motility with severe constipation.[68,69]

Before surgery, D.K. was taking oxycodone/acetaminophen for chronic low back pain. It is anticipated that D.K. will have opioid-induced constipation with postoperative opioid therapy. The docusate/senna dose that D.K. was taking before admission may need to be increased to two tablets twice daily for the management of increased constipation owing to more frequent opioid use for acute pain.

Case 55-2, Question 6: What oral short-acting opioid dose should D.K. be prescribed when discharged from the hospital?

As soon as D.K. can tolerate oral medication, the IV PCA dose should be discontinued and a short-acting oral opioid such as oxycodone or hydromorphone be administered prn with frequent reassessment of pain. Because D.K. is at high risk for respiratory depression, the lowest starting dose should be prescribed. Oxycodone 5 mg by mouth every 4 hours prn or hydromorphone 2 mg by mouth every 4 hours prn would be options in this case. Oral short-acting morphine is not recommended owing to concern for metabolite accumulation. LA oral formulations (ie, sustained release or extended release [ER]) and transdermal fentanyl patches should be avoided for acute pain in patients who cannot tolerate around-the-clock opioid administration for a prolonged period of time.[65]

Guidelines from the Centers for Disease Control and Prevention recommend that a short-acting oral opioid prescription of 3 days or less is sufficient for acute pain.[70] For surgical pain, there is not a consensus on the maximum quantity of oral short-acting opioid tablets for a discharge postoperative prescription. When D.K. is

ready for discharge, a prescription for a limited supply of short-acting oral opioid should be written to cover the duration of severe postoperative pain, but not exceeding 7 days. D.K. needs education on how to safely take the opioid medication because postoperative pain management is different from chronic pain management. Discharge instructions should instruct D.K. to not take oxycodone/acetaminophen for chronic pain until the postoperative opioid therapy course is discontinued. Any unused opioid from the postoperative prescription should be appropriately discarded in pharmacy disposal boxes or through drug take-back programs in the community.

Case 55-2, Question 7: What other nonopioid medications would be helpful in the management of D.K.'s postoperative pain?

Guidelines on postoperative pain management endorse the use of nonopioid medication. There is evidence that the combination of acetaminophen and NSAIDs is more effective than either drug alone in reducing pain and opioid consumption.[28] Acetaminophen is useful in treating mild-to-moderate nociceptive pain.[28] Perioperative oral acetaminophen at a dose of 975 mg on a scheduled frequency after surgery in adults with normal liver function is supported in the literature.[62] After the initial postoperative period, the dose should be reduced to 650 mg and administered on a "prn" frequency. Acetaminophen-induced hepatotoxicity, which can be life-threatening, has been associated with daily use >4000 mg/day. Over-the-counter (OTC) acetaminophen product directions and experts recommend a lower maximum of 3000 mg/day in adults when used for a longer duration exceeding 7 days. To reduce the risk of hepatotoxicity, patients who will need opioid therapy should not be prescribed combination products containing acetaminophen, such as oxycodone/acetaminophen or hydrocodone/acetaminophen. The use of IV acetaminophen has generally been reserved for patients who cannot take oral medications after surgery and cannot use NSAIDs because of increased risk of GI bleeding or renal

insufficiency. Most research indicates that there is no clear difference between IV and oral acetaminophen in reducing postoperative pain.[28,62,71,72]

Compared with acetaminophen, NSAIDs are more efficacious for reducing postoperative pain owing to their anti-inflammatory effects. Most of the oral nonselective NSAIDs are comparable in efficacy, so selection may be influenced by other factors, such as onset and duration, availability for use OTC, and adverse effects. Growing concerns related to the cardiovascular toxicity of OTC NSAIDs resulted in a PRECISION study conducted by the U.S. Food and Drug Administration (FDA) on the safety of celecoxib, ibuprofen, and naproxen.[73] A post hoc analysis of the PRECISION study randomized patients to receive celecoxib 100 to 200 mg by mouth twice daily, ibuprofen 600 to 800 mg by mouth three times daily, or naproxen 375 to 500 mg by mouth twice daily along with a proton-pump inhibitor. Patients using naproxen or ibuprofen experienced significantly higher risk of major toxicity than those using celecoxib, resulting in updated boxed warnings for cardiovascular and GI bleeding on NSAID product labels.[74] All NSAIDs are contraindicated in patients with a history of hypersensitivity, asthma, urticaria, or allergic-type reaction to aspirin or other NSAID; and are use in the setting of coronary artery bypass graft surgery.

For postoperative pain management, NSAIDs should not be used in patients with an estimated glomerular filtration rate of <60 mL/minute.[75] There remains uncertainty regarding the potential harm of NSAIDs with bone healing in patients who undergo surgery for orthopedic fractures and spinal fusion, so this decision needs to be made after discussions with the surgeon.[28,76] Refer to Chapter 43 Osteoarthritis, for more detailed information on NSAIDs.

IV ketorolac is a nonselective NSAID that is very effective in reducing postoperative pain. The recommended IV ketorolac dose for adult patients with normal renal function is 30 mg every 6 hours prn. The maximum duration for ketorolac administration is limited to 5 days to prevent adverse events related to GI bleeding with prolonged use. Ketorolac is contraindicated in advanced renal disease or patients at risk for renal failure owing to volume

depletion.[28,76] The Beers criteria recommends against using ketorolac in older adults.[77]

Gabapentin and pregabalin, also referred to as *gabapentinoids*, are neuromodulators that are helpful in reducing postoperative neuropathic pain. For patients who were not taking gabapentin or pregabalin for chronic pain before surgery, the lowest dose should be started for postoperative pain.[78] In December 2019, the FDA updated product labels warning that serious, life-threatening, and fatal respiratory depression may occur in patients using gabapentinoids. The risk may be increased with the concomitant use of opioids and other CNS depressants, conditions such as chronic obstructive pulmonary disease, and in older adult patients.[79] Caution should be used with gabapentin and pregabalin in patients with renal insufficiency as both require dose reduction based on creatinine clearance. Patients who were taking gabapentin or pregabalin for preexisting neuropathic pain before surgery should have their dose and frequency resumed as soon as possible after surgery to prevent uncontrolled chronic pain.[11]

Ketamine has been used for decades in the operating room and emergency department to induce and maintain general anesthesia during procedures. Analgesic properties of ketamine are derived from the NMDA receptor antagonist activity that prevents central sensitization of pain. Low-dose ketamine (ie, subanesthetic) is becoming increasingly popular postoperatively to improve pain control in patients with a history of chronic pain that is poorly responsive to traditional analgesic medications and to reduce subsequent risk adverse effects with acute opioid therapy. The use of low-dose ketamine is an appealing nonopioid pain control option for morbidly obese patients because it is almost devoid of respiratory depression and sedation side effects when administered in subanesthetic doses.[62] The common subanesthetic dose of ketamine for acute postoperative pain is 0.3 to 0.5 mg/kg IV bolus with or without an infusion (usually started at 0.1–0.2 mg/kg/hour) depending on the duration of analgesic response required for a patient.[80] For morbidly obese patients, ideal body weight should be used when calculating the ketamine dose.[62] Commonly reported side

effects of ketamine are nausea, vomiting, vivid dreams or hallucinations, and dissociative effects. Clinicians should consider limiting the use of ketamine in patients with poorly controlled psychiatric conditions involving psychosis, such as schizophrenia.

IV lidocaine, an amide local anesthetic and Class 1b antiarrhythmic, interacts with several receptors to prevent hypersensitization and hyperalgesia. IV lidocaine has been evaluated as part of multimodal analgesia in patients who underwent open or laparoscopic abdominal procedures. Data to support that perioperative or intraoperative IV lidocaine infusions are associated with shorter duration of ileus and reduction in postoperative opioid consumption compared to placebo are inconclusive.[81] In trials, lidocaine was typically administered as an IV bolus (100–150 mg or 1.5–2 mg/kg), followed by an infusion of 2 to 3 mg/kg/hour at the end of surgery.[81,82] IV lidocaine is generally not considered a first-line therapy for postoperative pain management with spine surgery.[83]

D.K. should have acetaminophen started at 975 mg orally scheduled every 8 hours for 2 to 3 days, then changed to 650 mg every 6 hours prn. The acetaminophen dose should be given separately from the oral opioid. Combination tablets containing opioid/acetaminophen increase the risk of acetaminophen toxicity with scheduled acetaminophen. Gabapentin is a good option for postoperative neuropathic pain. The dose and frequency of gabapentin should start low at 100 mg, then increased based on D.K.'s pain control in the absence of side effects. A low-dose ketamine infusion for 24 to 48 hours after surgery may be beneficial in reducing D.K.'s IV opioid use in the PACU and on the postsurgical unit, which could lower the risk for respiratory depression. Before D.K. is discharged, plans should be made for prescribing the oral multimodal medications for a short duration of time because moderate-to-severe postoperative pain is generally less intense after 1 to 2 weeks.

LOW BACK PAIN

Low back pain is the leading cause of disability worldwide, with a global point prevalence of 7.8%.[9] In the 2012 National Health Survey, low back pain was reported in 27.5% of U.S. adults in the past 3 months.[84] It has been reported that low back pain affects 70% to 85% of adults at some point in their lives, and 12 months after the onset of low back pain, 45% to 75% of people still have pain.[85,86] There is a bimodal distribution with peaks between the age of 25 and 29 years (2.58/1000 person-years) and between the age of 95 and 99 years (1.47/1000) without differentiation by underlying etiology.[85] There is an association between psychological factors and the occurrence of low back pain, including anxiety, depression, somatization symptoms, stress, and negative body image. Chronic low back pain patients have higher rates of emotional distress and depression (25%) compared to acute low back pain subjects (2.9%).[87] Socioeconomic risk factors include job dissatisfaction, physical work, psychologically stressful work, low educational achievement, and workers' compensation insurance.[88] Biomechanical and physical work factors such as heavy lifting, repetitive motion, and non-neutral body postures are established risks for back disorders.[86] Chronic low back pain also creates a large financial burden on the workplace. Low back pain accounts for almost $87.6 billion in total costs, the majority of which was lost wages and productivity, and patients who have been on disability for >1 year rarely return to work.[89]

Low back pain, by definition, affects the lumbosacral spine and associated muscles and nerves. It is multifactorial in nature, either nociceptive (musculoskeletal, myofascial), neuropathic (radicular pain), or has a central sensitization component.[90] In about 85% of cases, no pathophysiologic cause can be found.[86] The functional spinal unit is made up of two vertebral bodies, two zygapophyseal (facet) joints, the intervertebral disc, and the supporting ligamentous structures (**Fig. 55-5**). The facet joints of the spine form the junction where vertebral bodies meet. The joint space is maintained by cartilage and fluid in the joint. Like all weight-bearing joints of the body, the spine also develops joint space narrowing, bony hypertrophy, and deterioration of cartilage with normal use, resulting

in the musculoskeletal pain of OA. If the spine is used more, as with jobs involving heavy lifting and manual labor, the joints deteriorate faster. In addition to deterioration of the facet joint spaces, the intervertebral discs lose water content with time and may become desiccated, reducing the cushion between the vertebral bodies. These discs are fragile and can be torn or damaged and may herniate into the spinal canal foramen (Fig. 55-5). If vertebral bodies shift because of deterioration, spondylolisthesis may occur. This shift, or a herniated disc, may impinge on the spinal nerve root, or cause nerve root irritation, which can produce radicular neuropathic pain. This is sometimes referred to as *sciatica*. Shifting of the vertebral bodies may also reduce the size of the foramen where the nerves exit the spinal cord (spinal stenosis). If the vertebral bodies shift too far into the central spinal canal, pressure can be exerted on the spinal cord, which may lead to spinal cord injury and subsequent loss of sensory and motor nerve function (paralysis). If the motor nerves are affected (as with lower extremity muscle weakness, bowel or bladder incontinence), a “red flag” is present and surgery may be necessary to preserve function. **Table 55-9** lists other serious conditions that call for immediate medical or surgical attention.[91] Sometimes, low back pain is more intense than would be expected, or is much more widespread than imaging would predict. These are hallmarks of central sensitization.[90]

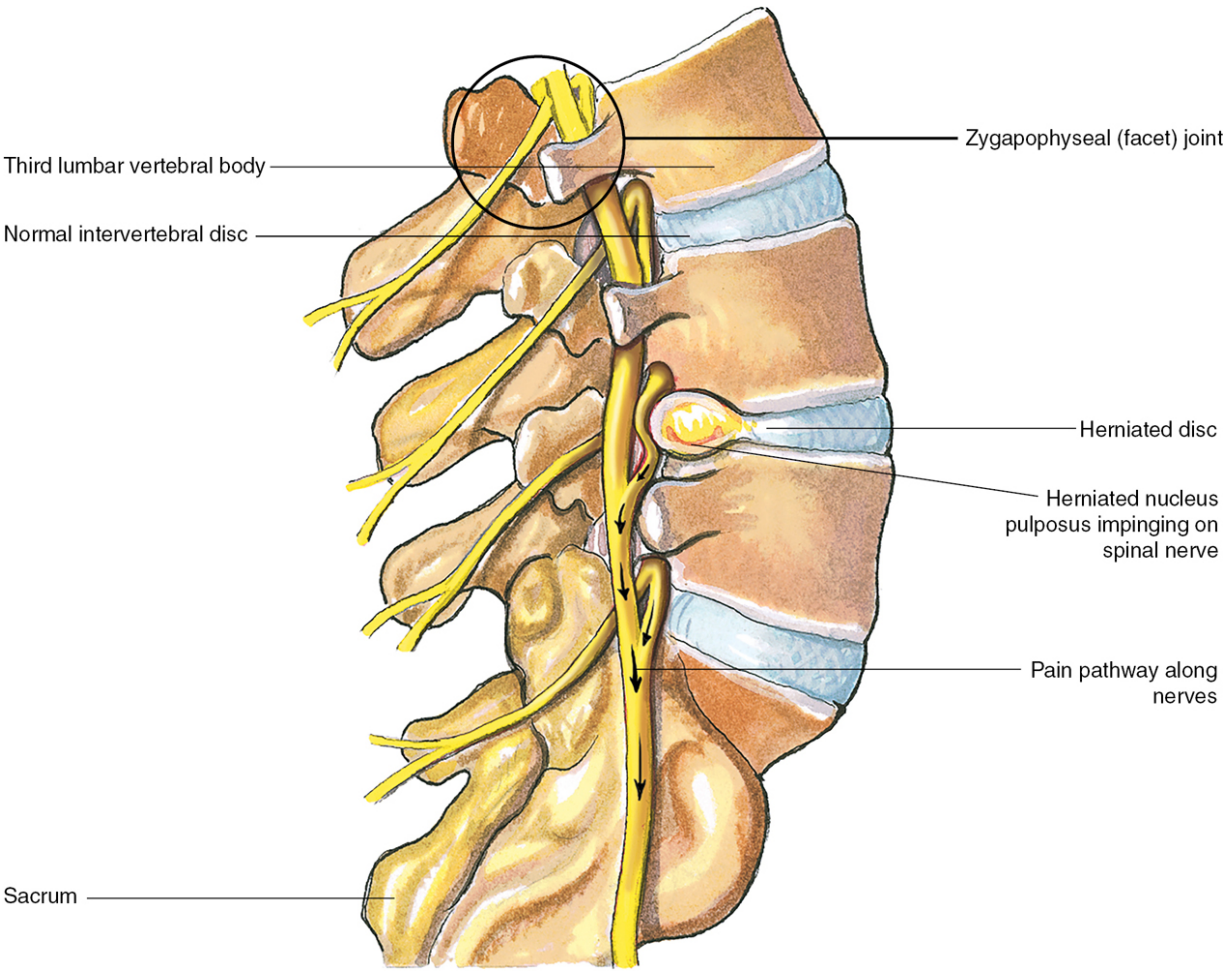

Figure 55-5 Spine anatomy and disc herniation.

Table 55-9
Red Flags for Potentially Serious Conditions That Cause Back Pain

Possible Fracture	Possible Tumor or Infection	Possible Cauda Equina Syndrome
Major trauma, such as vehicle accident or fall from height	Age <20 or >50 years	Saddle anesthesia
Minor trauma or strenuous lifting in older or potentially osteoporotic patients	History of cancer	Recent onset of bladder dysfunction (eg, urinary retention, increased frequency, overflow incontinence)

Possible Fracture	Possible Tumor or Infection	Possible Cauda Equina Syndrome
	Constitutional symptoms (recent fever, chills, unexplained weight loss)	Severe or progressive neurologic deficit in the lower extremities
	Risk factors for spinal infections: Recent bacterial infection IV drug abuse Immunosuppression	Unexpected laxity of the anal sphincter
	Pain that worsens when supine	Perianal/perineal sensory loss
	Severe nighttime pain	Major motor weakness: Quadriceps (knee extension weakness) Ankle plantar flexors, evertors, and dorsiflexors (foot drop)

IV, intravenous.

Myofascial pain is very common in patients with chronic low back pain. Myofascial pain is localized to specific regions or muscle groups. It affects all age groups and is associated with numerous other pain conditions. It is classically associated with muscle knots called “trigger points.” A trigger point is described as a hyperirritable spot in skeletal muscle that is associated with a palpable “taut band” of muscle. Trigger points are hypothesized to evolve from excessive acetylcholine release from the motor endplate, leading to sustained muscle fiber contracture. Development of trigger points is usually associated with mechanical overuse or overload of a muscle group (as with repetitive work). It is also associated with postural problems, prolonged static positions, emotional stress (causing muscles to tense), and nutritional deficiencies (such as vitamins B_1, B_6, B_{12}, and D; iron; magnesium; and zinc) or metabolic problems, such as

thyroid disease. It is thought that low-intensity exertions related to static posture cause small muscle fibers to be continuously activated, leading to the development of trigger points.[92] Nociceptors are abundant in muscle nerves, and there are a variety of nociceptors that can be stimulated by substances such as prostaglandins, bradykinins, protons, ATP, 5-HT, and glutamate, which are released from damaged tissue. The neuropeptides, substance P and CGRP, are also found in the nociceptor terminals, which stimulate the inflammatory cascade, leading to peripheral sensitization and the clinical manifestation of muscle pain. Continuous activation of muscle nociceptors leads to the release of substance P and glutamate from the presynaptic terminal at the dorsal root ganglion. These substances activate postsynaptic AMPA and NMDA receptors, respectively, and subsequently may lead to neuroplasticity (see Fig. 55-3).

Acetaminophen has traditionally been considered the safest choice for the management of musculoskeletal pain. Its mechanism of action is not well defined, but it has analgesic activity in the CNS. It has no peripheral clinical effect on prostaglandins, so it lacks typical anti-inflammatory activity. A meta-analysis of acetaminophen versus placebo for spinal pain and OA, however, found acetaminophen to be ineffective.[92] As a result, more recent guidelines suggest that NSAIDs should be the first-line medications for the treatment of acute or chronic low back pain.[93] NSAIDs reduce pain and inflammation by inhibiting cyclooxygenases (COX-1 and COX-2) at the site of injury and along the ascending pain pathway. The NSAIDs are equally effective across the drug class, although some patients may respond to one agent better than another. They are more effective as monotherapy for acute low back pain than in combination with a muscle relaxant or an opioid. A meta-analysis showed that NSAIDs are better than placebo for back pain without neuropathic symptoms, but not for back pain with neuropathic symptoms. COX-2 selective inhibitors are as effective as traditional NSAIDs for analgesia but are better tolerated.[94] Celecoxib is the only COX-2 selective inhibitor available in the United States.

Acetaminophen is often used in combination with NSAIDs for additive analgesia.

There are several guidelines published for the management of low back pain. Oliveira et al reviewed evidence-based management guidelines from 14 different countries and 1 multinational committee that were published between 2008 and 2017.[93] **Table 55-10** presents a summary of common recommendations. All guidelines were in agreement with the use of NSAIDs as the first-line therapy for both acute and chronic low back pain.

Table 55-10
Summary of Common Recommendations for Treatment of Low Back Pain

Acute or Subacute Pain
Reassure patients that diagnosis is not serious
Advise to stay active
Prescribe medication if necessary
First line: NSAIDs
Second line: muscle relaxants
Discourage bed rest
Do not recommend supervised exercise program
Chronic Pain
Discourage use of alternative therapies (ultrasound, electrotherapy)
Short-term use of medication/manipulation
First line: NSAIDs
Second line: Duloxetine or tramadol
Supervised exercise therapy
Cognitive-behavioral therapy
Multidisciplinary treatment

NSAIDs, nonsteroidal anti-inflammatory drugs.

From Oliveira CB, Maher CG, Pinto RZ, et al. Clinical practice guidelines for the management of non-specific low back pain in primary care: an updated overview. *Eur Spine J*. 2018;27(11):2791–2803. https://creativecommons.org/licenses/by/4.0/

Most guidelines recommend muscle relaxants only for acute low back pain either alone or in combination with NSAIDs. Despite the fact that muscle relaxants are used commonly, there is no evidence that they are effective for chronic low back pain. Agents such as cyclobenzaprine and tizanidine, as well as benzodiazepines such as diazepam, show moderate efficacy in the short term (<2 weeks) but are associated with a higher incidence of adverse effects than placebo.[95] For chronic low back pain, second-line treatment recommendations include either tramadol for short periods or duloxetine. Tramadol has also shown modest relief with short-term use (<4 weeks).[96,97] There are several studies showing some efficacy for most LA and short-acting opioids, but they do not show any long-term functional improvement or return to work.[98–100]

A few guidelines, including those from the American College of Physicians, recommend the use of duloxetine over other antidepressants or anticonvulsants for neuropathic pain symptoms.[96] Antidepressants, specifically the TCAs, have shown modest analgesia compared with placebo, but they have not been shown to be effective for acute low back pain, nor have they shown demonstrable improvement in function.[101] Duloxetine, an SNRI, has shown efficacy and safety for the treatment of low back pain.[102] There have been a very small number of trials using the anticonvulsants topiramate and gabapentin for back pain. Anticonvulsants traditionally have been helpful for treating neuropathic pain (eg, peripheral neuropathies) but produce only small improvements for back pain with radiculopathy.[103–105]

Myofascial pain treatment is aimed at correcting precipitating behaviors, including ergonomic factors. Physical rehabilitation is essential for teaching patients appropriate stretching and strengthening exercises, as well as postural support and stabilization. Some clinicians inject the trigger point(s). There are several techniques that are all equally effective, including dry needling, saline injection, local anesthetic injection, or botulinum toxin. Several other pharmacologic therapies may be used, but none have more than anecdotal support. General approaches to pain management, including NSAIDs, muscle relaxants, antidepressants,

anticonvulsants, and opioids, may be helpful for individual patients. Vitamin D deficiency has been linked to chronic musculoskeletal pain, although this is somewhat controversial.[106,107]

CASE 55-3

Question 1: J.P. is a 48-year-old male who presents with low back and leg pain. He has had chronic low back pain for several years, which has progressively worsened during the past several months. He reports an aching pain that is localized to his lumbosacral spine with some radiation into his buttocks and hips. He also describes burning pain into his right leg all the way down to his toes. He rates his pain as 7 out of 10 on the numeric pain scale. On good days, his pain is 5 of 10. He recently did some yard work and had an acute exacerbation of his pain. He reports that this felt like 10 out of 10 on the numeric pain scale, and he was in bed for the following 2 days because of pain. He is usually able to do some chores around the house, but activity makes his pain worse. He sleeps poorly (only about 4–5 hours/night), and he does not go out or socialize very often because he is afraid that this will exacerbate his pain. He used to golf and play softball but is not able to participate in these hobbies any more as a result of pain. He smokes two packs of cigarettes daily and drinks about a six-pack of beer each week. He was previously a plumber but had to quit his job earlier this year because of health problems. He denies any lower extremity weakness and loss of bowel or bladder control. He has not found anything that really helps his pain, except rest and acetaminophen/codeine that his sister gave him. His past medical history includes hypertension, hyperlipidemia, depression, and morbid obesity. His current medications are lisinopril for hypertension, simvastatin for hyperlipidemia, carisoprodol, cyclobenzaprine prn, low-dose aspirin, and acetaminophen/ codeine. He also takes three tablets of OTC strength (200 mg/tablet) ibuprofen and three tablets of extra strength (500 mg/tablet) acetaminophen about four times daily with minimal relief of his pain. Upon physical examination, J.P. has pain with palpation along his lumbar paraspinal muscles with several trigger points noted and marked tenderness at the level of L4–L5. His reflexes are intact, and he has full strength in his lower extremities. The remainder of his physical examination is unremarkable, except that general deconditioning is noted. There are no laboratory tests or imaging studies available. He reports that his blood pressure is usually around 150/80 mm Hg with a pulse around 75 beats/minute.

What are the clinically relevant findings (or absence of findings) for J.P.'s pain assessment, and how would you characterize his pain?

The presentation and assessment of back pain can be very complex, given its multifactorial nature. Acute low back problems are defined by the Agency for Health Care Policy and Research as "activity intolerance attributable to lower back or back-related leg symptoms of <3 months' duration."[108] J.P.'s acute exacerbation would fit this definition. When J.P. has acute exacerbations of his low back pain, the numeric pain scale is an accurate assessment tool (see Table 55-2 and Fig. 55-4). His rating of 10 out of 10 indicates severe acute pain. Clinicians should also consider a patient's vital signs, which may be elevated with acute pain. If a patient is unable to communicate (eg, on a respirator), changes in vital signs may be the only indicator of discomfort.

Assessment of chronic low back pain in this patient must rely heavily on the history he provides, because there is minimal objective evidence to base the assessment on, other than his findings on physical examination or imaging studies. He indicated that his chronic pain is about 7 out of 10 on the numeric pain scale. Even though the numeric pain scale has been validated for chronic pain, it is less useful in this setting because it only gives a snapshot of the whole pain picture. A multidimensional tool, such as the Brief Pain Inventory or the McGill Pain Questionnaire, is more useful to assess chronic pain (see Table 55-2).[17,18] Physical activities, sleep, diet, and social interactions may be affected by chronic pain. J.P. notes that his pain is worse with physical activity. He reports sleeping poorly and has limited physical activity and minimal social interaction. All of these factors contribute to a patient's pain experience and must be considered (see Fig. 55-1). Assessment of chronic pain is not only more complex, but is more extensive, because the perception and response to chronic pain is widely variable. Each patient experience with pain is individualized. A psychological assessment is essential to identify comorbidities such as depression or anxiety and any history of abuse (eg, physical, verbal, sexual) or previous trauma, as well as to assess a patient's coping ability. It may be helpful to ask J.P. about his spirituality and cultural values, because these may offer unique opportunities (or barriers) to any proposed treatment plan.

If opioids are being considered, many clinicians endorse the use of a screening tool such as the Screener and Opioid Assessment of Patients with Pain-Revised (SOAPP-R) or Opioid Risk Tool (ORT) to assess for the risk of misuse.[109] J.P. drinks alcohol, smokes tobacco, and has used his sister's acetaminophen/codeine. These factors may warrant the use of a screening tool to assess his risk for opioid misuse.

J.P.'s chronic pain has been present for several years and has gradually worsened. Based on his history and current physical examination, he appears to have mechanical musculoskeletal pain. He is a former plumber, which involves bending and lifting, which puts him at risk for facet joint arthritis. He describes the aching, localized pain that is typical of arthritis, either in his spine–hip junction (sacroiliac joint) or his zygapophyseal (facet) joints, which are the most common locations for lumbosacral pain. He demonstrated localized tenderness at the L4–L5 level. This is most consistent with facet joint disease. He also has tenderness along muscles in his low back, reaching into his buttocks, which is very common, because the body attempts to accommodate structural spine abnormalities. Muscular pain may radiate into the mid-back or into the buttocks, but does not travel below the knees. J.P. does not have any motor weakness, past experiences, or comorbidities that would indicate a red flag (see Table 55-9). J.P.'s physical examination reveals radicular pain in the L5 dermatome (ie, an area of the skin supplied by nerves from a single spinal root). Unlike muscular pain, radicular pain travels from the spine past the knee into the distal extremities. J.P. describes burning and shooting pain that radiates from his spine down his right leg to his toes. These are hallmarks of neuropathic pain. J.P. appears to have both musculoskeletal/myofascial and neuropathic pain. This mixed picture is very common with back pain and adds complexity to both diagnosis and treatment plans.

Case 55-3, Question 2: What comorbidities will affect J.P.'s presentation and pain assessment?

J.P. has a concurrent diagnosis of depression, which is quite common in patients with chronic pain. The incidence of depression in chronic pain patients is two or three times higher than the general population.[110] Depression is often underrecognized in the face of pain as a presenting symptom. Many times, health care providers investigate for a functional cause of the pain, but overlook the psychosocial aspects of pain. Variables associated with depression in chronic pain are female sex, younger age, lower socioeconomic status, unmarried, Caucasian, and higher pain severity.[111] In fact, because pain severity worsens, depressive symptoms worsen, medical visits become more frequent, and health care costs increase. The relative deficiency of NE and 5-HT that occur with depression makes the pain-blocking function of the descending pain pathway less effective. As a result, J.P. may feel more pain physiologically and may also have a greater emotional response to his pain and other stressors. His depression may be contributing to his sleep disturbance and his diminished social interactions. Untreated depression may be detected with a multidimensional pain assessment tool. If identified and treated, his pain may improve concurrently with his depression. Other psychiatric comorbidities that commonly occur with chronic pain include anxiety, personality disorders, and substance use disorder.

J.P. also has a diagnosis of hypertension. Although this will not directly contribute to his pain, any acute exacerbations may cause an increase in his pulse and blood pressure. Increases in blood pressure are associated with an increased incidence of stroke. The presence of hypertension is also a factor when developing a treatment plan. He is currently taking ibuprofen for pain, and NSAIDs are known to cause fluid retention, compromise renal function, and diminish the benefits of antihypertensives (such as lisinopril). Corticosteroids, which may be used during an interventional pain procedure, may also increase blood pressure.

CASE 55-3, QUESTION 3: How can current low back pain treatment guidelines be applied to J.P.'s pharmacologic regimen?

J.P. has been using acetaminophen up to 6000 mg daily, which exceeds the recommended maximum daily dose, and acetaminophen is no longer recommended for the treatment of low back pain. He has also been using some acetaminophen/codeine that he obtained from his sister. J.P. is at risk for liver toxicity from high doses of acetaminophen. In addition, he has not found the acetaminophen to be helpful, so it should be stopped. J.P. is also taking ibuprofen, which is recommended as the first-line therapy. He is taking 2400 mg daily without benefit. His pain relief is unlikely to improve with a dose increase, but he may benefit from rotation to another NSAID with a different chemical structure. Naproxen, meloxicam, etodolac, and celecoxib are all commonly used to treat inflammatory pain, but only naproxen is inexpensive and available OTC. He does not demonstrate any muscle spasm, so a muscle relaxant is not indicated, nor is it recommended for chronic low back pain. He has radicular pain, so a trial of gabapentin may be helpful, but duloxetine would be considered the first line for neuropathic pain in either acute or chronic low back pain. He has been using the codeine-containing product and notes that this has been helpful; however, opioids, other than tramadol, are not recommended for short-term or long-term management of chronic low back pain. He should be encouraged to reduce or discontinue use of the opioid. Selective serotonin reuptake inhibitors (SSRIs) may be used to treat depression, but have very little independent analgesic effects. However, if his depression improves, a proportional improvement in his pain would be expected. Because SSRIs are better tolerated than TCAs, and TCAs have not demonstrated improvement in function in the long term, J.P. should have a trial of a generic SSRI, such as citalopram. An SNRI, particularly duloxetine, would be the preferred antidepressant therapeutic option owing to its ability to treat both his depression and pain with fewer adverse effects than TCAs.

Case 55-3, Question 4: J.P. has been taking two different muscle relaxants for his back pain. He reports that neither of these is very helpful, and he usually does not have muscle spasms but does have trigger points on physical

examination. What would you recommend with regard to continuing these drugs? Would a trial of a different muscle relaxant be appropriate?

Muscle relaxants are commonly used to treat chronic musculoskeletal pain. They are recommended for short-term use for acute low back pain (all are fairly equal). A systematic review with fair quality evidence concluded that for the treatment of musculoskeletal pain, tizanidine, orphenadrine, carisoprodol, and cyclobenzaprine were more effective than placebo. There were not sufficient data of good quality to determine whether metaxalone, methocarbamol, chlorzoxazone, baclofen, or dantrolene was better than placebo for this indication.[95,96] At this time, guidelines do not recommend chronic use of muscle relaxants for musculoskeletal pain. There is a small study that shows improvement in myofascial pain with tizanidine, but there are no data supporting continued use of carisoprodol or cyclobenzaprine.[112] These agents belong to a chemically diverse family, but all work in the CNS, either in the brain or in the spinal cord. They are categorized as either antispasmodics or antispasticity agents. The *antispasmodics* are either benzodiazepines (eg, diazepam) or nonbenzodiazepines (eg, cyclobenzaprine) and are used for muscular pain and spasms associated with peripheral musculoskeletal conditions. The *antispasticity* agents reduce spasticity associated with upper motor neuron disorders, such as multiple sclerosis (eg, tizanidine, baclofen) (**Table 55-11**). Because J.P. has not experienced any improvement in his pain with previous trials of muscle relaxants, switching to another is not likely to yield any improvement in his symptoms, although tizanidine has shown some promise.

Table 55-11
Oral Muscle Relaxants

Drug	Oral Dose	Adverse Effects	Monitoring/Comments
Antispasmodic			
Cyclobenzaprine	5 mg tid, titrate to 10 mg tid	Dry mouth, constipation, urinary retention, somnolence, confusion, blurred vision	Also available in extended-release formulation Tricyclic structure and associated adverse effects
Metaxalone	800 mg tid–qid	GI upset, nausea, vomiting, dizziness, headache, somnolence, hemolytic anemia, leucopenia, jaundice	Contraindicated in anemia, liver impairment, renal impairment Monitor liver function, CBC
Methocarbamol	1500 mg tid, or 1000 mg qid	Itching, rash, indigestion, nausea, vomiting, dizziness, headache, nystagmus, somnolence, vertigo, blurred vision, arrhythmias, hypotension, leucopenia, urine discoloration	Monitor heart rate, blood pressure
Orphenadrine citrate	100 mg bid	Syncope, nausea, vomiting, dry mouth, dizziness, blurred vision, palpitations	Monitor CBC, liver function
Chlorzoxazone	500–750 mg tid–qid	Lightheadedness, dizziness, somnolence, malaise, liver toxicity	Monitor liver function
Carisoprodol	250–350 mg tid and at bedtime	Dizziness, headache, somnolence, respiratory depression	Monitor for weakness, dizziness, confusion, misuse, or abuse
Antispastic			
Tizanidine	4 mg tid, titrate to maximum of 12 mg tid	Hypotension, somnolence, muscle weakness	Monitor blood pressure, liver function
Baclofen	10 mg tid, titrate to maximum of 20 mg qid	Somnolence, muscle weakness, ataxia	

bid, two times a day; CBC, complete blood cell count; GI, gastrointestinal; qid, four times a day; tid, three times a day.

CASE 55-3, QUESTION 5: J.P. returns after 3 months with a small improvement in his back pain. He is sleeping a bit better (6 hours/night). He is attending physical therapy sessions, although infrequently. He has been taking citalopram 20 mg by mouth daily for his depression and feels that this is somewhat helpful for his mood. He has been taking naproxen 500 mg by mouth three times a day and gabapentin 300 mg by mouth three times a day for his pain. Neither of these has provided adequate relief. Another provider gave him a prescription for oxycodone 5 mg/acetaminophen 325 mg one to two tablets every 6 hours prn. J.P. has been taking two tablets every 6 hours on a regular schedule. This helps his pain (30% improvement and he notes that the addition of the opioid has allowed him to start working part time again as a handy male); however, the relief only lasts 3 to 4 hours and then he is in pain for another 2 to 3 hours before he can take another dose. He also reports a lot of nausea with this regimen. He has heard about "pain patches" and wonders whether these might be an option for him. J.P. is getting about 30% improvement with oxycodone/acetaminophen, which is a good response for any analgesic, but the duration of relief is short, and he is having nausea after each dose. He has asked about using a pain patch. What therapy might you suggest to optimize J.P.'s analgesia? Is a pain patch a good choice?

Although opioids are not recommended for chronic low back pain, J.P. has noted an improvement in pain and function.[113] The consequences of long-term opioid therapy are significant and have resulted in recent guidelines discouraging their use. If all first- and second-line therapies have been or are currently being trialed without adequate relief, it would be reasonable to consider continuing his analgesic combination as long as evidence of improved function justifies continued use. There are several analgesic options available for patients who are unable to tolerate or ingest solid oral dosage forms (tablets and capsules). It is common for patients with feeding tubes and patients who have maxillofacial surgery to use alternative dosage forms, such as oral liquids, topicals, or transdermal products. J.P. has asked about a pain patch. It is likely that he is referring to either a fentanyl transdermal system or a buprenorphine patch. These agents offer extended delivery options, but are often not cost-effective; therefore, a pain patch may not be the best choice for J.P. Because he is able to take oral medications, it would be most reasonable to rotate to an oral opioid that offers a longer duration of action. When considering product rotation for J.P., it is important to consider drug formulation and availability, route of administration, drug interactions, adverse effects, and cost. The oxycodone/acetaminophen product that he is currently using is not providing an adequate duration of analgesia. He may need to use an ER/LA opioid to achieve sustained analgesia. There are many ER/LA opioid formulations available, including morphine (tablets, capsules), oxycodone (tablets), hydromorphone (capsules), methadone (tablets), oxymorphone (tablets), hydrocodone (capsules, tablets), buprenorphine (patch, buccal film), and fentanyl (patch). Several of these agents are formulated with abuse-deterrent technologies. Because he is getting good pain relief with oxycodone/acetaminophen, converting to an ER formulation of oxycodone seems the most logical choice. J.P. is currently taking eight 5-mg tablets of oxycodone daily (40 mg total per day). This may be directly converted to ER oxycodone 20 mg orally twice daily, with elimination of the short-acting product. If he continues to have nausea after his doses of oxycodone, he may need to rotate to

another opioid or use a nonoral route of administration, an antiemetic, or a nonopioid analgesic.

J.P. has been using several different analgesics for his pain, including an NSAID, an anticonvulsant, an antidepressant, and an opioid. These agents will offer pharmacologic activity at several points in the pain pathway (see Fig. 55-2) and offer additive analgesic effects.[114,115] However, multimodal therapy also carries the risk of additive adverse effects and possible drug interactions. For example, the anticonvulsant and the opioid may cause additive sedation. The balance between adverse effects and analgesia must be considered with any changes in drug therapy. He is also taking lisinopril. Using an NSAID concurrently with an angiotensin-converting enzyme inhibitor or an angiotensin-receptor blocker may cause hyperkalemia or acute renal blood flow compromise. A nonacetylated salicylate such as salsalate or diflunisal may offer analgesia with a lower risk potential and fewer adverse effects and drug interactions. They have minimal effects on prostaglandin production.

Case 55-3, Question 6: J.P. returns 6 months later, after seeing a pain specialist and a psychologist. He is now taking gabapentin 1200 mg by mouth three times a day, meloxicam 7.5 mg by mouth once daily, amitriptyline 25 mg by mouth every night at bedtime, and oxycodone controlled-release (CR) 20 mg by mouth twice a day. How should J.P.'s therapy be monitored?

Clinicians must assess each part of J.P.'s care plan, both the positive aspects and the negative aspects. Is J.P. meeting his goals on his personal care plan? Is he getting more sleep? Is he more physically active? Is he managing his stressors better? Is his pain improved? There are several monitoring tools that may be used routinely to record long-term progress. The "5 As" of monitoring therapy are often used: analgesia, activities of daily living, adverse effects, affect, and potential aberrant drug-related behavior.[116]

In addition to monitoring for efficacy, assessing for adverse effects of his medication is critical. Gabapentin may cause sedation, dizziness, edema, and cognitive impairment of short-term memory,

concentration, and word finding. Meloxicam, an NSAID, may cause GI upset or ulceration, so he should be advised to watch for black, tarry, sticky stools or any sign of internal bleeding. He may experience easy bruising and bleeding related to the platelet inhibitory effects of NSAIDs and should have his serum creatinine and potassium checked regularly to monitor for NSAID-induced renal toxicity. His blood pressure should also be monitored regularly because this has been elevated in the past. Oxycodone may cause constipation, sedation, dry mouth, and urinary retention. If he is using the opioid regularly, he should be advised to also use a bowel regimen with a stool softener, osmotic laxative, or a motility agent. In addition, if he is using the opioid for an extended period of time, he may need to have his testosterone levels checked and bone density testing done periodically to monitor for hypogonadism and osteoporosis, which are associated with chronic opioid therapy. Amitriptyline may cause additive sedation, constipation, and urinary retention. He is unlikely to have problems with orthostatic hypotension, but this is common in older patients.

Case 55-3, Question 7: What nonpharmacologic therapies may be beneficial for J.P.'s pain?

Oliveira et al found that most guidelines recommend exercise therapy, cognitive-behavioral therapy (CBT), and short-term pharmacologic therapy.[93] Recent guidelines emphasize insufficient or mixed evidence to recommend specific therapies for radicular pain.[91,96] Epidural steroid injections, radiofrequency ablations, and, possibly, surgery may be considered in patients with persistent radicular low back pain with specific spinal pathology but are discouraged for nonspecific low back pain. Because J.P. has radicular pain into his legs and he has tried the first-line therapies, he may be a candidate for an epidural steroid injection. This will only offer temporary relief, at best, but may provide him with enough relief to participate more in physical rehabilitation. Studies show mixed results with both invasive procedures (ie, injections, laser therapies,

spinal cord stimulators) and surgery, so J.P. must be part of the decision-making process.[92,96]

In the past, patients were advised to use bed rest for acute back pain; it is now recommended that patients remain physically active. This has been shown to improve pain and function at 3 to 4 weeks compared with bed rest.[96,117] Bed rest is also not recommended for chronic back pain. J.P. still has limited physical activity and was noted to be deconditioned. Inactivity can increase muscular pain. Physical rehabilitation is a key component of management, but there is no difference in benefit among different forms of exercise, so J.P. may choose a program that best fits his interests and needs. Physical rehabilitation also may include stretching and strengthening, but these are less effective when used outside a comprehensive exercise program. Heat wraps are recommended for acute low back pain with moderate evidence, whereas other modalities such as cold packs to reduce inflammation in the acute phase of an injury have no evidence supporting their use. Spine manipulation, low back corsets, and acupuncture have shown some efficacy, but other physical modalities such as massage, ultrasound, traction, or shoe lifts have not been shown to be effective.[96] J.P. may report that he has more pain after he starts an exercise regimen, because his muscles will be reconditioned. J.P. should be encouraged and given assurances that physical activity that is at an appropriate level for his needs may cause him to hurt but will not harm him. He can also learn how to pace his activities so he does not overdo it with yard work as he has done in the past.

CBT and mindfulness-based stress reduction (MBSR) have been shown to improve back pain and functional limitations.[118] Mental health care is an essential component of multidisciplinary pain management. CBT works on a patient's perception of pain and expectations, focusing on mood, catastrophizing, negative thinking, and poor coping skills. MBSR focuses on increasing awareness and acceptance of moment-to-moment experiences, including physical discomfort and difficult emotions. After J.P.'s depression is addressed, he can work with a therapist on coping skills and how to use self-regulation and manage stressors.

NEUROPATHIC PAIN

Pain may be centrally or peripherally mediated. Peripheral sensory neuropathy usually involves injury or insult to peripheral nerves, such as postherpetic neuralgia (PHN), which affects spinal nerve dermatomes. The pain tends to be fairly localized, either regionally or along an associated dermatome. Central pain syndromes originate from injury to the CNS or alteration in central pain processing, as occurs with neuroplasticity. Central pain presents with a larger affected area, up to and including unilateral, head-to-toe pain that may be seen after a stroke. Poststroke pain is a central pain syndrome, caused by a lesion in the CNS. Sometimes, the cause of central pain syndromes cannot be identified, and even though a stroke presents with a specific lesion, it is still very difficult to treat. However, by far, the most difficult and far-reaching pain is central neuropathic pain generated in the CNS, which is called *central poststroke pain* (CPSP). CPSP has been reported in as many as 25% of stroke survivors.[119] The diagnostic criteria for CPSP are as follows: (a) pain in an area of the body corresponding to the lesion of the CNS, (b) history suggestive of stroke and onset of pain at or after stroke onset, (c) confirmation of a CNS lesion by imaging or negative or positive sensory signs confined to the area of the body corresponding to the lesion, and (d) other causes of pain, such as nociceptive or peripheral neuropathic pain, that are excluded or considered highly unlikely.[119] The clinical presentation of CPSP is similar to other neuropathic pain. The onset of pain ranges from immediate to several months after stroke. It may affect a small region of the body or a large area (from head to toe). Central pain after a contralateral stroke is quite common, particularly after thalamic strokes (eg, patients with a stroke in the left side of the brain will have symptoms on the right side of the body). Because the thalamus is the brain's "relay station," any abnormal signaling may be amplified.[120] Temperature-sensory dysregulation via the spinothalamic tract is common, as well as dysesthesias and allodynia. It is described as "burning," "aching," "squeezing,"

"pricking," or "cold." These symptoms are frequently aggravated by a cold environment, psychological stress, heat, fatigue, or body movement.

There are no guidelines for the management of CPSP, and few robust studies exist but lack data related to comparative efficacy. Therapy is usually selected on a trial-and-error basis. The strongest evidence currently supports the use of lamotrigine (titrated to 400 mg/day).[121] Some data support a trial of amitriptyline (with titration from 10 up to 100 mg/day), or nortriptyline may be used as an alternative TCA in patients who do not tolerate amitriptyline.[122] SNRIs have been shown to be beneficial for other types of neuropathic pain, but not for CPSP. If pain relief is insufficient, an anticonvulsant may be used. Other anticonvulsants that have shown efficacy for both central and peripheral neuropathic pain are listed in **Table 55-12**.[123] Opioids have been studied in patients with CPSP but were not effective, and there was a high withdrawal rate.[124] Nonpharmacologic therapies for CPSP include deep brain stimulation, motor cortex stimulation, and transcranial magnetic stimulation. Physical rehabilitation (physical and occupational) is essential to help improve function, and CBT is used to help patients cope with their new circumstances and cognitive or physical limitations.

Table 55-12
Anticonvulsant and Neuromodulator Options for Treatment of Neuropathic Pain

Drug	Oral Dose[a]	Adverse Effects	Monitoring/Comments
Carbamazepine[b]	200 mg tid, titrate to maximum of 400 mg tid	Diplopia, rash, hepatitis, neutropenia, aplastic anemia, dizziness, cognitive effects, hyponatremia	Check LFTs, CBC, sodium at baseline and every 3 months during therapy, periodic serum levels
Oxcarbazepine	75 mg bid, titrate to maximum of 1200 mg bid	Rash, cognitive effects, hyponatremia, sedation, blurred vision, nausea	Check sodium every 2 weeks for 3 months, then with dose increases
Lamotrigine	25 mg daily, titrate to maximum 200 mg bid	Desquamating rash, cognitive effects	Requires very slow titration to avoid rash
Topiramate[b]	25 mg bid, titrate to maximum of 200 mg bid	Nausea, anorexia, paresthesias, metabolic acidosis, cognitive effects, nephrolithiasis	Check serum bicarbonate at baseline and every 3 months or with each dose increase
Gabapentin[b]	300 mg daily, titrate to maximum of 1200 mg tid	Somnolence, dizziness, edema, cognitive effects	Reduce dose for renal impairment or older adults
Pregabalin[b]	75 mg bid, titrate to maximum of 300 mg bid	Same as gabapentin	Same as gabapentin

bid, two times a day; CBC, complete blood cell count; ECG, electrocardiogram; LFTs, liver function tests; tid, three times a day.

[a]All oral agents are titrated up to reduce adverse effects and titrated down when discontinuing therapy.

[b]The Food and Drug Administration approved for treating pain conditions.

Herpes zoster occurs in 6.1 per 1000 Americans each year, and ~20% of these patients experience PHN.[125] Evidence-based guidelines for treating neuropathic pain have been published by several international organizations in the past several years.[20] Most studies have been conducted in PHN and DPN, because these are the most common neuropathic pain conditions. Some types of neuropathic pain (eg, spinal cord injury and human immunodeficiency virus neuropathy) have been quite resistant to pharmacologic therapy. Studies to date have shown only partial relief of neuropathic pain, regardless of pharmacologic treatment. Doses, adverse effects, and monitoring for these agents can be found in Tables 55-11 and **55-13**.

First-line treatments for neuropathic pain include antidepressants such as SNRIs and TCAs. These antidepressants demonstrate effective pain relief, even in patients without concurrent depression. TCAs are inexpensive and easily administered once daily; however, they have significant anticholinergic adverse effects, such as dry mouth and constipation that many patients do not tolerate. The secondary amine TCAs, like nortriptyline, have fewer anticholinergic adverse effects than the parent compound amitriptyline and are similarly effective. TCAs are known to cause orthostatic hypotension and urinary retention in older adult patients and may cause cardiac arrhythmias with higher doses. Venlafaxine functions as an SSRI at low doses and needs to be titrated by 37.5- or 75-mg increments each week to reach a target dose of at least 200 mg daily. At this dose, venlafaxine offers SNRI activity. However, at higher doses (>225 mg/day), increases in blood pressure and heart rate caused by increased NE activity may cause patients to stop therapy. Duloxetine has shown efficacy in treating neuropathic pain with doses of 60 to 120 mg/day.[126] Cardiac rhythm, blood pressure, and

pulse rate do not seem to be affected by duloxetine. The most common adverse effect with duloxetine is nausea on initiation and sweating. The dose of duloxetine is titrated up over 2 weeks to minimize the nausea. Duloxetine is contraindicated in patients with liver disease or those who drink alcohol, because there have been reports of liver failure with this medication.[127]

Anticonvulsants that bind to voltage-gated calcium channels are also considered the first-line therapies for C fiber–related neuropathic pain (such as DPN and PHN), allodynia, and nonpainful dysesthesias (ie, abnormal sensations). They have also been very helpful in reducing central sensitization by preventing the release of glutamate and blocking glutamate receptors. Gabapentin and pregabalin (gabapentinoids), both voltage-gated calcium-channel blockers, have shown efficacy and are FDA approved for treating neuropathic pain, including PHN and DPN.[128–130] These agents must be taken two or three times daily and may cause dizziness, somnolence, peripheral edema, and cognitive problems. The somnolence is usually managed with a slow titration, but these combined effects may be significant in older adult patients. Although neither agent has many significant pharmacokinetic drug interactions, the doses must be reduced for renal insufficiency, because they are mostly renally eliminated.

Anticonvulsants that block sodium channels, such as carbamazepine, oxcarbazepine, and lamotrigine, have been shown to be helpful for Aδ fiber–mediated pain such as trigeminal neuralgia that has sharp, shooting qualities. Carbamazepine is an older agent that requires routine monitoring of complete blood counts for blood dyscrasias, liver transaminases for possible hepatitis, and serum sodium for possible syndrome of inappropriate antidiuretic hormone–induced hyponatremia. It is also a strong CYP enzyme inducer, and there are numerous drug–drug interactions with carbamazepine. Oxcarbazepine has substantially fewer drug interactions and does not require significant laboratory monitoring because it does not form the same 10,11-epoxide metabolite as carbamazepine; however, monitoring of serum sodium for the first 3 months of therapy and periodically thereafter is required. Lamotrigine has few drug

interactions, except with valproic acid, and does not require any laboratory monitoring. It may, however, cause a desquamating rash (eg, Stevens–Johnson syndrome) if the dose is escalated too quickly. A newer agent, lacosamide, shows modest efficacy for treating DPN but is not FDA approved for treating pain.

Topical agents such as local anesthetics and capsaicin are effective for treating localized areas of neuropathic pain, such as PHN. The 5% lidocaine patch available by prescription is approved by the FDA for the treatment of PHN and is particularly helpful for treating allodynia. There is a 4% lidocaine patch available OTC for the treatment of musculoskeletal pain. The lidocaine patch is very well tolerated and easy to apply. The patch may be cut to the desired shape and minimal local anesthetic penetrates the skin, so there is no systemic toxicity with proper administration. Other topical lidocaine products are available (eg, ointments and creams), but most do not penetrate the skin deep enough to reach the affected nerve endings. Capsaicin depletes substance P in the periphery and downregulates the TRP vanilloid 1 receptors. Because it is derived from chili peppers, it causes a significant amount of burning until the substance P is depleted, and many patients do not tolerate the application of the cream several times daily to accomplish this. Capsaicin cream is available in several strengths, and there is an FDA-approved 8% patch available for medical office use that is applied for an hour under local anesthesia and can be reapplied once every 3 months.[131]

Opioid analgesics have shown moderate efficacy at best in treating neuropathic pain and are not usually considered the first-line therapy because of potential long-term effects, such as hyperalgesia, tolerance, immunosuppression, and hypogonadism with osteoporosis.[20,21] Tramadol and tapentadol, atypical opioids, have both opioid and SNRI activity and have been shown to be effective in several types of neuropathic pain. Their adverse effects are similar to those of both opioids and SNRIs, including constipation, sedation, and, possibly, seizures, which are a dose-limiting effect.[20,132]

When compared in a systematic review and meta-analysis, all of the first-line agents and most second-line agents were equally

effective, with no significant differences in safety.[20]

There are some data that show that a combination of agents, such as an opioid and a gabapentinoid, or a TCA and a gabapentinoid, may offer more analgesia than either agent alone.[114,115] This polypharmacy may offer additive analgesia because different agents act on different parts of the pain-signaling pathways. If more than one agent is used, lower doses of each may reduce adverse effects. However, polypharmacy adds complexity to regimens, which may reduce compliance and cause confusion, particularly in older adult patients.

Atypical Opioids in Neuropathic Pain

When targeting neuropathic pain, atypical opioids with their complex mechanisms may provide solutions to refractory neuropathic pain that are often unresponsive to usual care. Tramadol is a recommended treatment option for low back pain, which is considered a mixed pain state with components of both nociceptive and neuropathic pain, but it is commonly utilized to augment treatment for various neuropathic pain conditions.[96] Tramadol is considered a prodrug because the parent molecule has low affinity for μ-opioid receptors (6000 times less than morphine) but, when metabolized via CYP2D6, undergoes a significant upgrade in potency to 200 to 300 times less affinity compared to morphine. This is comparable to potency of codeine in patients who are not poor metabolizers and have a functioning CYP2D6 enzyme.[133] The NE reuptake inhibition of tramadol increases potency and utility for targeting neuropathic pain. However, tramadol also contributes significant serotonergic activity that increases risk of seizures, serotonin syndrome, and is highly susceptible to drug interactions as a substrate of CYP3A4 and CYP2D6.[134] Tapentadol was designed to overcome the deficiencies of tramadol and is FDA approved for DPN.[135] Tapentadol has minimal serotonergic activity while maintaining NE reuptake ability, avoids significant CYP metabolism, and has decreased drug interactions, which improve predictability of

patient response. In addition, tapentadol is a schedule II opioid in part because of its significantly increased potency compared to tramadol with μ-opioid receptor affinity 18 times less than morphine and, when combined with NE reuptake inhibition, results in two to three times less potency than morphine.[136]

Methadone is a unique opioid with a complex mechanism including significant potency at the μ-opioid receptor, NE reuptake inhibition, and NMDA antagonism.[137,138] Utilizing methadone is a multimechanistic approach in a single medication, but its use is often restricted to pain specialists because of significant risk for harm compared to other opioids. Factors that increase risk of treatment with methadone include significant drug interactions, QTc prolongation, and complex pharmacokinetics, resulting in drug accumulation and higher risk of overdose if not used appropriately.[139,140] The half-life of 15 to 60 hours and high lipophilicity means a tissue reservoir develops, and steady state is not reached until a patient has taken methadone for 5 to 7 days after initiation or dose adjustment.[141] These factors combined result in complicated transitions when starting or stopping methadone therapy. Methadone equianalgesic conversions are complex and variable and should be performed by a pain specialist.

Postherpetic Neuralgia

CASE 55-4

Question 1: K.J. is a 73-year-old male with a history of Hodgkin lymphoma. He is in remission after chemotherapy and radiation treatment. He is seen in consult for PHN attributable to a case of shingles during chemotherapy. The zoster episode was after his first chemotherapy cycle 2 years ago. The lesions covered an area around his right lower abdomen below the umbilicus in a 10- to 15-cm strip around the lower back and buttock. At rest, his pain is a 1 to 2 out of 10 on the numerical pain scale. At its worst, it is 7 to 8 out of 10. Pain is aggravated by light touch or any jarring motion (such as riding in a car) or rubbing of clothes on the location of the zoster. He has two areas that have greater pain, one located in the lower right aspect of his back and the other in the right lower abdominal quadrant. He describes the pain as a burning

sensation. He gets mild relief from topical aquaphilic ointment. If he stays busy, it sometimes takes his mind off the pain. He has not been sleeping well because of the pain. His past medical history includes Hodgkin lymphoma (in remission), low back pain, and benign prostatic hypertrophy (BPH). He currently takes acyclovir 400 mg by mouth once daily, alprazolam 0.25 mg by mouth every night at bedtime prn for sleep, docusate 100 mg by mouth twice daily prn for constipation, multivitamin one tablet by mouth once daily, tamsulosin 0.4 mg by mouth every night at bedtime, and zolpidem 5 mg by mouth every night at bedtime. K.J. is married, has never smoked, and denies alcohol and illicit drug use. His physical examination is unremarkable, with the exception of scarring noted from the right lower abdomen to the back. Laboratory results and vital signs obtained at this visit are the following:

Serum creatinine, 1.2 mg/dL
Electrolytes, within normal limits
Blood pressure, 137/80 mm Hg
Heart rate, 77 beats/minute
Weight, 176.37 pounds (80 kg)

Which of K.J.'s presenting symptoms are consistent with neuropathic pain and PHN?

K.J. is past the acute phase of his herpes zoster (shingles) pain, but now notices that the pain has a burning quality, localized over the region where his lesions have healed. This is quite typical for a PHN presentation. Another feature that indicates a neuropathic type of pain is his increase in pain with light touch or rubbing of his clothing (allodynia). It is a localized pain that does not radiate past the dermatomal distribution of his zoster infection. Opportunistic infections such as herpes zoster are common in patients who are immunocompromised such as K.J. when he was receiving chemotherapy.

Postherpetic Neuralgia Treatment

CASE 55-4, QUESTION 2: What factors need to be considered when choosing a medication for K.J.? Which medication is the most appropriate option for treating K.J.'s PHN pain?

The 2004 American Academy of Neurology guidelines for PHN treatment state that TCAs (eg, amitriptyline, nortriptyline, and desipramine), gabapentin, pregabalin, opioids, and topical lidocaine patches are effective and should be used in the treatment of PHN.[142] Since that time, there have been many more studies published, but there has been very little change in the approach to treating neuropathic pain. The International Association for the Study of Pain has also published guidelines on the general treatment of neuropathic pain.[20]

Ideally, patients should be treated with the most effective therapy that has the lowest risk of adverse effects. K.J. has peripheral neuropathic pain in a localized area, which is typical of PHN, so a reasonable first-line choice would be a lidocaine patch. His pain is in a 10- to 12-cm strip that covers a large surface area from his abdomen to his back. He would need to use at least two patches daily to cover this area, which is fewer than the maximal recommended dose of three patches daily, and would be an effective barrier against the pain of clothing rubbing against this location. Another localized option would be capsaicin (as either a patch or a cream). Capsaicin cream is available OTC and is substantially less expensive than lidocaine patches. Insurance plans may require a trial of capsaicin before approving the more expensive lidocaine patch. Unfortunately, many patients cannot tolerate the burning associated with capsaicin.

Another first-line option would be a TCA, which may help him sleep. However, he has BPH, and the anticholinergic effects of a TCA may cause increased urinary retention. These medications also cause orthostatic hypotension and may be a risk for K.J. if he has to get up during the night to use the bathroom (see Table 55-13). An SNRI such as duloxetine would have fewer anticholinergic adverse effects but is not FDA approved for treating PHN.

Table 55-13
Common Antidepressants for Neuropathic Pain or Functional Pain Syndromes

Drug	Oral Dose[a]	Maximum Daily Dose	Adverse Effects	Monitoring/Comments
Tricyclic Antidepressants (TCAs)				
Amitriptyline	25 mg qhs	150–300 mg	Dry mouth, constipation, urinary retention, orthostatic hypotension, somnolence	Caution in older adults
Nortriptyline	25 mg qhs	50–150 mg		
Serotonin-Norepinephrine Reuptake Inhibitors (SNRIs)				
Duloxetine[b]	30 mg once daily × 1 week, then titrate to 60–120 mg	120 mg	Nausea, dry mouth, headache, diarrhea constipation, fatigue, sweating, anorexia	Contraindicated with liver disease or concurrent alcohol consumption. Monitor liver transaminases
Venlafaxine, extended release	37.5 mg once daily	225 mg	Headache, nausea, sweating, sedation, hypertension, seizures, tachycardia	Serotonergic effects <150 mg and noradrenergic effects >150 mg Monitor blood pressure and heart rate
Milnacipran[b]	12.5 mg on day 1; 12.5 mg bid on days 2 and 3, 25 mg bid on days 4–7, and 50 mg bid after day 7	100–200 mg	Nausea, headache, constipation, insomnia, hot flashes	Monitor blood pressure, heart rate

bid, two times a day; qhs, every night at bedtime.

[a]All oral agents are titrated up to reduce adverse effects and titrated down when discontinuing therapy.

Source: Cooper TE, Derry S, Wiffen PJ, Moore RA. Gabapentin for fibromyalgia pain in adults. *Cochrane Database Syst Rev.* 2017;1:CD012188.

As new medications are considered to address PHN, the risk of polypharmacy and additive adverse effects is significant and must be considered. K.J. takes both alprazolam and zolpidem for sleep, which represents a duplication of therapy and the potential for more severe adverse events, particularly when combined with sedating medications such as gabapentinoids, TCAs, or opioids. A calcium-channel blocking anticonvulsant such as gabapentin is a possibility. The sedating effects of gabapentin may help him sleep if his last dose is given at bedtime and would not cause the urinary retention, constipation, and orthostatic hypotension associated with TCA use. Given his age, a slow dose escalation starting at 100 mg by mouth three times a day would be appropriate. Upon initiation of gabapentin, alprazolam should be tapered and discontinued. As gabapentin is titrated to a therapeutic dose, zolpidem use should be reassessed and discontinued if possible. A disproportionately higher dose of gabapentin may be utilized at night to improve sleep and pain coverage without risking daytime sedation or dizziness. The

most important aspect of monitoring for this agent would be for cognitive effects, such as short-term memory problems or difficulty with word finding.

If the abovementioned options do not provide adequate analgesia, addition of an opioid such as morphine or oxycodone may be considered owing to the potential for additive analgesia. Opioids have synergistic effects with gabapentin that result in improved analgesia and some increased risk, resulting in an FDA warning in 2019 that the combination can result in respiratory depression and should be monitored carefully.[143] Initially, a short-acting opioid should be used so that K.J. may be titrated to the optimal analgesic dose. Opioids should not be initiated if he remains on benzodiazepines because there are 4 to 10 times increased risk of overdose with combination therapy.[144,145] Tramadol is another alternative with some TCA-like activity and mild opioid effects. However, if an opioid is added, it may increase the adverse effects of the abovementioned agents, including constipation, sedation, urinary retention, and cognitive effects. Whenever an opioid is added to a medication regimen, a bowel regimen must be implemented as well. A commonly used regimen includes a stool softener such as docusate sodium 100 mg by mouth twice daily or an osmotic agent such as polyethylene glycol 17 g by mouth daily and a mild stimulant laxative such as senna 8.6 mg one to two tablets by mouth once daily.

Modifying the Neuropathic Pain Regimen

Case 55-4, Question 3: K.J. returns after 2 months stating that he could not tolerate the burning of the capsaicin cream and so discontinued use. He is currently taking gabapentin 1200 mg by mouth three times daily and tramadol 50 mg one tablet by mouth four times daily. He continues to have 5 out of 10 burning pain over his right abdomen and back. He states that he has felt drowsy and has “unclear thoughts” with the gabapentin and does not feel that it has been very effective, despite titrating this to the maximal dose of 3600 mg daily. His wife reports that he is withdrawing from friends and he does not feel as involved. He is sleeping better, however, and believes that the tramadol is somewhat helpful in “taking the edge off” his pain. Given this information, what would be an appropriate adjustment in his therapy?

Adverse cognitive effects, such as problems with memory, concentration, and word finding, are common with anticonvulsants, especially in older patients. No anticonvulsant is better than any other in this regard; however, some of the adverse effects are dose related, and patients may exhibit tolerance to some of the effects (like sedation) with time. K.J. is at the maximal recommended daily dose of gabapentin and does not feel that this has been very helpful. At this time, he may need to be tapered off the gabapentin. Sometimes, patients do not notice analgesic effects of their medications until they are discontinued. It is a good practice to titrate oral analgesics upward when starting therapy and downward when discontinuing, to avoid a marked increase in pain and withdrawal syndromes that have been reported with both antidepressants and some anticonvulsants. He could reduce his dose by 300 mg every 3 to 5 days until his pain increases or he is off the gabapentin.

A different topical agent would be the lidocaine patch. Because he and his wife are reporting some signs of depression, an antidepressant may be an option. An antidepressant was not chosen previously because of concerns about his BPH symptoms; however, an SNRI such as duloxetine may be an effective alternative to treat his depression as well as his pain, although there are no studies reporting its effectiveness for this indication. Another option may be to switch to another anticonvulsant. Pregabalin has very similar pharmacologic activity to gabapentin, so it may not offer any additional analgesia over gabapentin. Possibly, a sodium-channel blocking anticonvulsant such as oxcarbazepine could be used for a trial. However, there are minimal data supporting the sodium-channel blockers for typical C fiber–mediated pain associated with PHN.

Case 55-4, Question 4: K.J.'s doctor decides to prescribe duloxetine and a lidocaine patch and taper off the gabapentin as tolerated. When the doctor orders K.J.'s new regimen, a drug–drug interaction listed between duloxetine and tramadol is identified. What recommendations are appropriate with regard to the potential drug–drug interactions with analgesics and, in particular, with K.J.'s regimen? What changes to his regimen could be suggested?

Analgesic Drug–Drug Interactions

Antidepressants either increase the concentrations of NE or 5-HT or both. Opioids also have serotonergic effects, so it is possible to have a net excess of either of these neurotransmitters or both. The consequence of an excess of NE is CNS excitation and possible seizures. The consequence of an excess of 5-HT is a possibly life-threatening syndrome called *serotonin syndrome.* Symptoms of serotonin syndrome include muscle rigidity, hyperpyrexia, mental status changes, and possible organ failure. None of these serious adverse effects are very predictable, although they are more likely with higher doses of either agent. If opioids are used with antidepressants, the lowest effective doses should be used, and patients should be counseled to watch for mental status changes.

Pharmacodynamic interactions are more likely to occur with analgesic polypharmacy. Because several analgesics may be used together to decrease the excitatory effects of the pain signal, there is always a risk of additive sedation, dizziness, or even respiratory depression. Several pharmacokinetic drug–drug interactions may occur with analgesics as well. In K.J.'s case, his duloxetine and tramadol are both substrates of CYP2D6 and may compete with each other for this enzyme. This may alter the blood levels and clinical effects of these agents. K.J. likely needs an antidepressant for his depression symptoms, so alternatives will need to be considered.

FUNCTIONAL PAIN SYNDROMES

FPSs are a cluster of disorders for which the pathophysiologic mechanisms have not been clearly defined to explain the symptoms.[146] FPSs include medically unexplained symptoms for both GI and non-GI disorders, such as dyspepsia, irritable bowel syndrome, fibromyalgia, chronic fatigue, and interstitial cystitis. There can be overlap in the syndromes with the presentation of

chronic pain and associated psychiatric comorbidities, including depression, anxiety, and posttraumatic stress disorder.[147,148] Somatic symptoms associated with significant distress and disruption of daily life are common with FPS. Patients with FPS often have health concerns manifested by disproportionate and persistent thoughts of serious symptoms, a high level of anxiety about symptoms, and excessive time and energy devoted to health concerns.[149–151]

Fibromyalgia

Fibromyalgia is a chronic debilitating condition with the primary symptoms of chronic widespread pain and fatigue. It affects between 3 and 6 million people in the United States, with an incidence of 4.9% in females and 2.9% in males.[152] Out-of-pocket health care costs for patients with fibromyalgia are three times higher than those without fibromyalgia.[153] According to guidelines by the American College of Rheumatology, all of the following must be met for the diagnosis of fibromyalgia: (a) generalized pain in at least four or five regions of the body, (b) symptoms present for at least 3 months, (c) Widespread Pain Index (WPI) ≥ 7 and Symptom Severity Scale (SSS) score ≥5 or WPI of 4 to 6 and SSS score ≥9, and (d) the absence of exclusion of a diagnosis of fibromyalgia in the presence of other clinically important illnesses.[154] The WPI quantifies bodily pain on a 0 to 19 scale and consists of asking patients if they have tenderness or pain in any of 19 different body regions over the past week. The SSS uses a scale of 0 to 3 in three categories: fatigue, waking unrefreshed, and cognitive symptoms, to assess a patient's level of pain over the past week.[155]

Fibromyalgia was previously thought to be peripherally mediated pain related to an inflammatory or muscular disorder, but new research into the pathophysiology is uncovering mechanisms associated with central sensitization owing to neurotransmitter dysfunction. Studies have shown an imbalance in neurotransmitters in which excitatory neurotransmitters in the CNS of fibromyalgia patients are increased, including glutamate (a twofold increase) and

substance P (a threefold increase), whereas inhibitory neurotransmitters (NE and 5-HT) are decreased. Patients with fibromyalgia have an enhanced perception of pain at substantially lower threshold and at a lower frequency of stimulation than control patients.[156] Input may be from the periphery or may be triggered by a central stimulus, such as a stressor. Heightened sensitivity to lower stimulus seems to contribute to the persistent pain.[157] This can be widespread, and symptoms seem to be largely affected by an exaggerated response to personal stressors, noxious stimuli (hyperalgesia), and non-noxious sensory stimuli (allodynia).

Fibromyalgia, as an FPS, is associated with other comorbidities that need to be addressed for symptom management, even though treating these symptoms may not directly benefit the hallmark tenderness associated with the syndrome. There is a high incidence of comorbidity between fibromyalgia, chronic fatigue syndrome, depression, and irritable bowel syndrome, and some have postulated that the gut–brain axis could be the common denominator. Communication between the gut and the CNS may be through the vagus nerve, enteric nervous system, endocrine system, and/or the immune system.[158,159]

Mental health conditions, such as depression and anxiety, may be present in 25% to 65% of patients with fibromyalgia.[160] Early life experiences (eg, verbal, sexual, or physical abuse), adult stressors (eg, divorce, bereavement), lack of social support, and other social learning experiences can affect an individual's physiologic and psychological responses.[151] The changes in these responses can lead to maladaptive learned-illness behaviors and predispose to functional GI and psychiatric disorders.[161]

CASE 55-5

QUESTION 1: G.R. is a 38-year-old female who presents with chronic widespread muscle pain from her neck down past her buttocks. She also has headaches when her pain is severe. She has had this pain for several years and notes that her pain developed after a car accident in which she sustained a whiplash injury. She describes difficulty sleeping, poor concentration, and fatigue. Her pain rating is 8 out of 10 on most days. She works part time doing

some home transcription. She has not identified anything that helps her pain, and physical activity makes the pain worse, so she does not exercise. Her pain is also worse when she is stressed. She was previously told that she has fibromyalgia, and while others have told her that "it's all in her head." Her past medical history includes depression and irritable bowel syndrome. She has tried ibuprofen, cyclobenzaprine, carisoprodol, and acetaminophen in the past without relief. She is currently taking tramadol 50 mg by mouth four times daily, which provides about 20% pain relief. She is also taking sertraline for depression. G.R. is married and has three children. She smokes one pack of cigarettes daily but denies drinking alcohol or using illicit drugs. She reports that her mother and sister have fibromyalgia and depression. She reports diffuse tenderness to palpation along her paraspinal muscles bilaterally, as well as her bilateral trapezius and levator scapulae muscles and her hips bilaterally. Several tender points are elicited. Her only remarkable laboratory result is vitamin D, 24 ng/mL (normal >30 ng/mL).

What part of G.R.'s presentation supports the presence of a FPS?

G.R. likely has fibromyalgia, given her widespread pain that has been present for >3 months and was precipitated by a traumatic event (car accident). She reports sleeping poorly, fatigue, and the comorbidities of depression and irritable bowel syndrome. On physical examination, she exhibits widespread musculoskeletal tenderness, including, but not limited to, several of the identified fibromyalgia tender points, bilaterally, both above and below the waist. Her vitamin D level represents a mild deficiency.

CASE 55-5, QUESTION 2: What pharmacologic and nonpharmacologic therapies could be recommended for G.R.?

There have been several evidence-based guidelines published for the treatment of fibromyalgia. Management should take the form of a graduated approach with the aim of improving health-related quality of life and focus first on nonpharmacologic modalities.[155,162,163] Among the nonpharmacologic therapies, exercise is highly recommended, particularly given its effect on pain, physical function, and well-being. A meta-analysis evaluated different regimens of aerobic activity and found that land- and water-based aerobic exercise, at a slight to moderate intensity, two to three times a week

for at least 4 weeks resulted in improvement of depressed mood and increased health-related quality of life scores and physical fitness. This was maintained if the patient continued exercise at home.[164] Aquatic training is beneficial for improving wellness, symptoms, and fitness in adults with fibromyalgia.[165] Luciano et al found that CBT is more cost-effective than routine FDA-approved medications for adult fibromyalgia patients.[166]

Psychological therapies should be considered for patients with mood disorder or unhelpful coping strategies. CBT has been found effective at producing modest, long-term reductions in pain and disability and improving mood.[162] Bernardy et al conducted a systematic review of CBT for fibromyalgia and found that this therapy improves coping with pain and reduces depressed mood and health care–seeking behavior.[167]

Pharmacologic therapies should be considered for patients with severe pain. Because evidence indicates a CNS neurotransmitter imbalance, the most effective pharmacologic approaches have targeted these imbalances. Antidepressants have been shown to reduce pain and improve function by increasing the levels of 5-HT and NE in the CNS. Historically, TCAs (most commonly amitriptyline) have been shown to moderately improve pain, sleep, and, to a smaller extent, fatigue and health-related quality of life. Although cyclobenzaprine is indicated for muscle spasms, studies have indicated its weak TCA effects may help with sleep in patients with fibromyalgia.[162] Studies on mirtazapine at 15 to 45 mg daily found that pain was not substantially reduced with fibromyalgia.[168] Duloxetine and milnacipran are both SNRIs that are FDA approved for fibromyalgia. A comprehensive review of SNRIs in the treatment of fibromyalgia concluded that a minority of patients may experience pain relief with duloxetine or milnacipran but neither SNRI improved quality of life with fatigue reduction.[169] Hauser et al compared duloxetine, milnacipran, and pregabalin in fibromyalgia and found that duloxetine and pregabalin were better than milnacipran in improving pain and sleep.[170] Duloxetine was better for symptoms of depression, and pregabalin and milnacipran were better for fatigue. Headache and nausea were more common with duloxetine and

milnacipran, and diarrhea was more common with duloxetine. Tramadol has demonstrated only a slight improvement in pain. Evidence on the efficacy of SSRIs for improvement of pain is weak, so they are not recommended.[162]

Gabapentinoids have been shown to reduce the activity of excitatory neurotransmitters, particularly glutamate. Pregabalin is an anticonvulsant that was approved by the FDA in 2007 for treating fibromyalgia. It targets the increased levels of glutamate in the CNS by binding to the $a_2\delta$ subunit of voltage-gated calcium channels, preventing the release of glutamate from presynaptic terminals (see Fig. 55-3). This agent has been shown to improve average pain scores and patient perception of improvement but failed to show improvement in Fibromyalgia Impact Questionnaire scores.[171,172] An analysis of randomized controlled trials found that pregabalin was effective in treating fibromyalgia, and results were observed within 1 to 2 days of starting treatment.[173] Gabapentin, a similar compound, has not been formally approved for fibromyalgia but has support for its use. Some insurance companies require a trial with gabapentin before allowing use of pregabalin because of its lower cost. A recent systematic review concluded that there is insufficient evidence to support or refute observations that gabapentin reduces pain in fibromyalgia.[174]

NSAIDs, acetaminophen, and opioids are not recommended for treating fibromyalgia pain.[162,175] In fact, Goldenberg et al conducted a literature review and found no evidence from clinical trials that opioids are effective for the treatment of fibromyalgia. The studies reviewed found that patients with fibromyalgia receiving opioids had poorer outcomes than those receiving nonopioids.[176]

An appropriate first step for G.R. is to develop a multidisciplinary approach, including physical rehabilitation, CBT, and pharmacologic therapy adjustments. She is currently taking an antidepressant (sertraline), which may be helpful for her depression but is likely not very helpful for her fibromyalgia. It may be possible to switch her to an SNRI such as duloxetine or milnacipran in consultation with her mental health provider. She is currently taking tramadol with some

relief. She has not maximized her dose (maximum daily dose is 400 mg); however, she is also taking an SSRI, which may place her at a higher risk of serotonin syndrome. The risks and benefits of combining antidepressants with tramadol must be considered on a patient-by-patient basis. Because she is having trouble sleeping, she could be offered a trial of amitriptyline or pregabalin, both of which have sedating side effects (see Tables 55-12 and 55-13).[177] Pregabalin is a recommended agent and has a different mechanism of action than the medications that she has previously tried. If cost of therapy is a concern, then gabapentin could be tried instead. A vitamin D supplement should also be considered to correct her slightly low vitamin D levels. There is not strong evidence supporting vitamin D supplementation, but there is little harm in correcting her slight deficiency.

Psychological Comorbidity and Opioid Risk Management

CASE 55-6

Question 1: M.T. is a 33-year-old female with chronic abdominal pain. She first experienced recurrent episodes of abdominal pain at the age of 13 after menarche. At age 21, she was diagnosed with acute pancreatitis secondary to alcohol use. Her pain has persisted despite numerous trials of medications, including gabapentin, sertraline, tramadol, and hydrocodone/acetaminophen. She has undergone multiple diagnostic evaluations for the abdominal pain, but all have resulted in negative findings. During the past year, M.T. has had eight visits to the emergency department for severe pain where she usually receives a discharge prescription for five tablets of oxycodone/acetaminophen 5 mg/325 mg. In addition to the emergency department visits, she has been hospitalized three times in the past year for abdominal pain.

Today, M.T. is being seen in the clinic by her primary care physician for continued management of chronic abdominal pain, which she describes as "constantly aching." Over the past 2 years, M.T.'s primary care physician has been prescribing oxycodone in conjunction with an opioid agreement focused on minimizing the use of emergency department visits for pain management. M.T. believes her current management with oxycodone 5 mg by mouth every 4 hours prn for severe pain is insufficient and would like the 30-day supply limit increased from 180 to 240 tablets.

The primary care physician is concerned about M.T.'s functional status since starting opioid therapy. There has been no noticeable improvement in M.T.'s pain despite three increases in the 30-day oxycodone supply over the past 2 years. During the office visit, M.T. is emotionally labile at times and tearful when discussing her pain but is emphatic that she is not depressed. She states that she drinks one or two "highballs" (whisky and soda) about two times a week to help her relax when she is feeling "stressed out." M.T. denies smoking or illicit drug use. She is currently unemployed and seeking permanent disability because the pain interferes with her ability to work. Her physical examination is unremarkable, except for diffuse abdominal tenderness.

What is the clinical relevance of M.T.'s self-description of abdominal pain?

CLINICAL RELEVANCE OF ABDOMINAL PAIN

The prevalence of chronic abdominal pain ranges from 0.5% to 25% of the population.[111] M.T.'s self-report of pain is consistent with centrally mediated abdominal pain syndrome (CAPS).[175] CAPS is more common in females and peaks around the fourth decade of life. Patients with CAPS have high work absenteeism and health care utilization.[147,179] Key features in the diagnosis of CAPS include abdominal pain that is present for at least 6 months and is not related to GI function. Patients will often have a decrease in daily activity with time. The principal criterion differentiating CAPS from other GI disorders, such as pancreatitis or irritable bowel syndrome, is constant pain that lacks symptom relationship to food intake or defecation. Psychological disturbances are more likely when pain has persisted for a long period and manifests as symptom-related behaviors that dominate a patient's life (**Table 55-14**).[149,179]

Table 55-14

Symptom-Related Behaviors of Centrally Mediated Abdominal Pain Syndrome (CAPS)

Expressing pain of varying intensity through verbal and nonverbal methods
Urgent reporting of intense symptoms disproportionate to available clinical and laboratory data
Minimizing or denying a role for psychosocial contributors, anxiety, depression; attributing symptoms of anxiety or depression to presence of pain
Requesting diagnostic studies to validate the condition as "organic"

Focusing attention on complete relief of symptoms
Seeking health care frequently
Taking limited personal responsibility for self-management
Making requests for opioid analgesics when other treatment options have been implemented

Source: Derry S, Wiffen PJ, Häuser W, et al. Oral nonsteroidal anti-inflammatory drugs for fibromyalgia in adults. *Cochrane Database Syst Rev.* 2017;3:CD012332.

From the physiologic perspective, M.T.'s abdominal pain most likely originated from a combination of peripheral and visceral components. When the pain symptoms occur frequently in conjunction with a stressor as in CAPS, the main mechanism for altered pain regulation relates to the failure to inhibit the amplification of normal regulatory afferent input from the gut to central mechanisms in the prefrontal, cingulated cortex, and limbic structures in the brain (eg, cognitive and emotions centers). This impairment in homeostatic inhibition of pain may be related to low levels of 5-HT, NE, endorphin, and other neuropeptides that mediate descending pain transmission in the CNS. Recognition of the brain–gut axis in CAPS is essential to understanding its clinical presentation, diagnosis, and therapeutic strategies.[14,146] A new condition in the spectrum of CAPS is narcotic bowel syndrome characterized by incompletely controlled abdominal pain that cannot be explained by another known or previous diagnosis in patients receiving steady or increasing doses of opioids. Abdominal pain caused by narcotic bowel syndrome is centrally mediated visceral hyperalgesia rather than GI dysmotility.[161] Narcotic bowel syndrome is often under diagnosed by clinicians and can be the underlying cause of chronic abdominal pain. Patients typically report poorly localized, moderate-to-severe constant abdominal pain despite starting opioid therapy, and the pain gets worse as the opioid dose is increased. The phenomenon of pain getting worse with escalating opioid doses is called *opioid-induced hyperalgesia*. Successful treatment must include reducing the opioid dose.[178] Clinicians need to understand that most patients with narcotic bowel syndrome might not see reduction of opioids as a logical option. M.T. believes that

opioids have been the most helpful pain treatment and fears being perceived as “drug seeking” or having a psychiatric problem. The primary care physician will need to communicate each time this conversation occurs with M.T. that despite using high-dose opioids, the benefit is incomplete and describe the value of other treatments (eg, antidepressants).

CENTRALLY MEDIATED ABDOMINAL PAIN TREATMENT

CASE 55-6, QUESTION 2: What are the current recommendations for pharmacologic treatment of CAPS? What approaches to the management of CAPS are appropriate for M.T.?

The cornerstone to pain management depends on an effective relationship between the clinician and the patient. In this case, the primary care physician needs to listen to M.T.’s concerns, ask questions like “How do you believe I can be helpful to you?” and have a conversation about realistic expectations for ordering tests, medical interventions, and medications. M.T. needs to be an active participant in the pain management plan and take responsibility for self-care.[178]

Pharmacotherapy for patients with CAPS is empirical and not based on results from well-designed clinical trials. Clinical trials have not been targeted to this diagnostic entity, so treatments are typically designed on the basis of data from other chronic pain disorders. Antidepressants, such as TCAs in low daily dosages, may be useful in treating CAPS for both pain and depression owing to their combined noradrenergic and serotonergic effects. In other chronic pain conditions, TCAs generally have been more successful than using SSRIs.[179] Medications with combined 5-HT and NE reuptake activity (eg, SNRIs such as venlafaxine and duloxetine) have recognized pain-reducing effects with visceral pain conditions and may be useful in CAPS. For patients who are refractory to usual doses of antidepressant medication, referral to psychiatry should be made for treatment with atypical antipsychotic agents such as

quetiapine. Quetiapine has been used in lower doses for treating patients with anxiety, sleep disturbance, and associated psychological comorbid symptoms.[180] To ensure treatment adherence, M.T. needs affirmation that the antidepressant is not prescribed simply to treat depression. It is important that the clinician educate the patient on the role of antidepressants in the treatment of pain. Patient education resources such as diagrams help to show the physiologic basis for treatment of pain and describe descending inhibitory pathways.[149,179]

Gabapentin and pregabalin clinical trials have established their efficacy for neuropathic pain and fibromyalgia, but benefit for visceral or central pain syndromes is not established. NSAIDs offer little benefit because their action is located in the peripheral nervous system. Long-term treatment with benzodiazepines is not recommended because of the abuse potential and tendency to interact with other medications.[149,179]

RISK OF ADDICTION

Case 55-6, Question 3: There is concern about M.T.'s use of alcohol and escalating use of opioid medication. What is the risk that M.T. will become addicted to opioids?

Opioid use behaviors are stratified based on the risk of aberrant drug use. Aberrant drug use behaviors may occur along a spectrum from those less suggestive of addiction, such as an occasional, sanctioned increase in the opioid dose by a medical provider, to those that may be more suggestive of addiction, such as concurrent illicit drug use. **Table 55-15** provides a list of risk factors for opioid misuse.[19,181,182] Important but less consistent risk factors include pain-related functional impairment, such as sleep disturbance, mental health issues, history of child sexual abuse or neglect, and legal problems. With respect to gender, females with chronic pain who report significant emotional issues were at increased risk for opioid misuse.[182,183]

Table 55-15

Risk Factors for Opioid Addiction

Concurrent abuse of alcohol or illicit drugs
Selling medication
Stealing medication
Injecting oral formulations
Multiple dose escalations or other nonadherence with therapy despite warnings
Obtaining prescription drugs from nonmedical sources
Prescription forgery
Repeated resistance to changes in therapy despite clear evidence of physical or psychological effects
Repeatedly seeking prescriptions from other prescribers or emergency departments
Selling prescription drugs
Stealing or borrowing drugs from others

Sources: Kaye AD, Jones MR, Kaye AM, et al. Prescription opioid abuse in chronic pain: an updated review of opioid abuse predictors and strategies to curb opioid abuse: part 2. *Pain Physician*. 2017;20:S111–S133; Keefer L, Drossman DA, Guthrie E, et al. Centrally mediated disorders of gastrointestinal pain. *Gastroenterology*. 2016;150(6):P1408–P1419; Clouse RE, Mayer EA, Aziz Q, et al. Functional abdominal pain syndrome. *Gastroenterology*. 2006;130:1492–1497.

M.T. has multiple behaviors in which some are more indicative of addiction such as concomitant alcohol use whereas others can be explained, given the etiology of CAPS. For example, high health care utilization for pain validation is common in patients with CAPS. Also, aggressive about the need for more opioid medication may be driven by M.T.'s perception that the current dose prescribed by her primary care physician no longer relieves her pain, implying tolerance has developed (**Table 55-16**).[182,183]

Table 55-16

Terms Related to Opioid Use

Term	Definition

Term	Definition
Misuse	Taking a prescription for a reason or at a dose or frequency other than for which it was prescribed. Use of a medication for a nonmedical use. For example, altering dosing or sharing medicines, which has harmful or potentially harmful consequences.
Abuse	Misuse with consequences involving the use of a substance to modify or control mood or state of mind in a manner that is illegal or harmful to oneself or others. Potentially harmful consequences include accidents, injuries, blackouts, legal problems, and sexual behavior that increase the risk of infectious diseases.
Addiction	A primary, chronic, neurobiologic disease with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving.
Physical dependence	A state of adaptation manifested by a drug class–specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, or administration of an antagonist.
Tolerance	A state of adaptation in which markedly increased drug doses are required to achieve desired effect or exposure results in diminution of one or more opioid effects over time.

Sources: Clouse RE, Mayer EA, Aziz Q, et al. Functional abdominal pain syndrome. *Gastroenterology*. 2006;130:1492–1497; Potvin S, Morin M, Cloutier C, Gendron A, Bissonnette A, Marchand S. Add-on treatment of quetiapine for fibromyalgia: a pilot, randomized, double-blind, placebo-controlled 12-week trial. *J Clin Psychopharmacol*. 2012;32:684–687.

The factor that is most concerning for addiction is M.T.'s continued use of alcohol despite previous pancreatitis and misusing it to treat anxiety. There is also a risk of increased opioid side effects, especially sedation and respiratory depression, with concurrent use of alcohol. Multiple literature reports have confirmed there is a strong association between alcohol abuse and opioid addiction.[181,182] Guidelines for chronic opioid therapy strongly recommend clinicians conduct a risk assessment before initiating opioid therapy.[70,181]

Screening tools that assess the potential risks for opioid misuse based on patient characteristics are helpful in determining eligibility for chronic opioid therapy. Patient self-report questionnaires for assessing risk of aberrant drug-related behavior include the SOAPP-R, ORT, Alcohol Use Disorder Identification Test, and Drug Abuse Screening Test.[19,181]

ASSESSMENT OF CHRONIC OPIOID THERAPY

CASE 55-6, QUESTION 4: M.T. would like to continue with opioid therapy despite the concerns of her primary care physician. Is M.T. a candidate for chronic opioid therapy?

The Centers for Disease Control and Prevention released recommendations for opioid therapy that support the establishment of a treatment plan with the patient before starting opioid therapy that includes realistic goals for pain and function along with consideration of when therapy will be discontinued if benefits do not outweigh risks. Clinicians should continue opioid therapy only if there is clinically meaningful improvement in pain and function that outweighs risks to patient safety.[70] In the case of M.T., a pain agreement (eg, contract) should be established even if the goal is to eventually discontinue opioid therapy. There are multiple sources in the literature for information and guidelines on written agreements between the clinician and patient for chronic opioid therapy.

The written agreement should include goals of therapy, how opioids will be prescribed and taken, expectations for follow-up and monitoring, alternatives to therapy, expectations regarding use of concomitant therapies, and potential for tapering the regimen and discontinuing.[19] Indications for tapering and/or discontinuation of the opioid include failure to make progress toward therapeutic goals, intolerable adverse effects, or repeated or serious aberrant drug-related behaviors. Patient compliance requirements in the written agreement should include random urine drug screens for illicit substances or opioids obtained from other sources and limited

prescribing (eg, reduced quantities, biweekly prescribing) to help the patient manage use if necessary. In this case, M.T. has not made progress in meeting the goal of decreased emergency department utilization, she continues to use alcohol with her medication, and she has been resistant to trying other therapies despite the ineffectiveness of opioids in treating her pain. These behaviors would indicate M.T. is not a candidate for chronic opioid therapy.

DISCONTINUING OPIOID THERAPY

Case 55-6, Question 5: M.T. is going to be discontinued from opioids as part of the pain management plan. What methods are appropriate to safely discontinue opioid therapy in M.T.?

Guidelines strongly recommend that clinicians taper patients from chronic opioids if they have repeated aberrant drug-related behaviors, experience no progress toward meeting therapeutic goals, or experience intolerable adverse effects.[19,70] When tapering patients from long-term opioid therapy, the length of time the patient has been taking opioids needs to be considered. Approaches to opioid tapering range from a slow 10% dose reduction per week to a more rapid 25% reduction every few days. Evidence to guide specific recommendations on the rate of reduction is lacking, although the slower rate may help reduce the unpleasant symptoms of opioid withdrawal.[19]

There is insufficient evidence to guide recommendations for the use of short-acting versus LA oral opioids, or prn versus around-the-clock dosing during taper.[184] In this case, it is recommended that M.T.'s oxycodone dose be reduced slowly over 2 months in conjunction with starting psychological therapy for stress management and counseling for alcohol use. M.T. will need to be monitored for signs of withdrawal, which include anxiety, tachycardia, sweating, and other autonomic symptoms. Should withdrawal symptoms occur, they may be lessened by clonidine 0.1 to 0.2 mg by mouth twice a day.

COGNITIVE-BEHAVIORAL THERAPIES

Case 55-6, Question 6: What nonpharmacologic therapies could be offered to M.T. to help with her pain management?

Psychological counseling and CBT are key components to successful management of the patient. The psychological approach to CBT has been shown to be beneficial in the treatment of CAPS.[178] CBT typically combines stress management, problem-solving, goal setting, pacing of activities, and assertiveness into a strategy for self-management of pain. Biofeedback, meditation, guided imagery, and hypnosis can all be incorporated into a CBT plan (**Table 55-17**). The objective is to help patients acquire a sense of hopefulness and resourcefulness and develop positive coping skills.[185]

Table 55-17
Cognitive-Behavioral Therapy

Meditation—intentional self-regulation of attention using a systematic focus on particular aspects of inner and outer body experience.
Biofeedback—self-regulatory technique that teaches a patient how to exert control over the physiologic processes exacerbating pain. Biofeedback equipment conveys physiologic responses as visual or auditory signals that the patient can observe on a computer monitor. With practice, the patient learns to control and change his/her physiologic responses by manipulating the auditory or visual signals.
Guided imagery—useful method to help patients with pain to relax and achieve a sense of control and distraction. This modality involves the generation of different mental images, evoked either by oneself or with help from the practitioner.
Hypnosis—a state of heightened awareness and focused concentration that can be used to manipulate the perception of pain.

Source: Kaye AD, Jones MR, Kaye AM, et al. Prescription opioid abuse in chronic pain: an updated review of opioid abuse predictors and strategies to curb opioid abuse: part 1. *Pain Physician*. 2017;20:S93–S109.

Complementary and alternative therapies such as spinal manipulation, massage, and acupuncture are commonly used in

patients with chronic pain, but data supporting their use in CAPS are limited. Transcutaneous electrical nerve stimulation has been studied in CAPS patients, but the results are inconclusive.[178,185]

Care of the Critically Ill Adult

Philip Grgurich, Adrian Wong, and John Marshall

CORE PRINCIPLES	CHAPTER CASES
HOME MEDICATIONS IN THE INTENSIVE CARE UNIT	
1 Medications used to treat chronic conditions are often administered in the intensive care unit (ICU) as long as it does not provide harm to the patient. The decision to continue or hold medications that cause bleeding (eg, warfarin, clopidogrel), have hemodynamic effects (eg, blood pressure medication), have hypoglycemic effects (eg, diabetes medications), and/or that can potentially interact with medications administered in the ICU is made on an individual basis based on risk and benefit.	**Case 56-1 (Question 1)** **Case 56-2 (Question 1)**
PHARMACOKINETICS OVERVIEW AND DRUG SELECTION	

1	Available pharmacokinetic data are often determined in healthy subjects. Critically ill patients may have significant changes in all pharmacokinetic parameters. The clinician should be attuned to those disease states most likely to induce alterations and to develop appropriate monitoring and management strategies for specific medications.	**Case 56-3 (Questions 1–7)**
PAIN, AGITATION, AND DELIRIUM		
1	Pain, agitation, and delirium commonly occur in critically ill patients for a variety of reasons. Clinicians should vigilantly assess patients for pain and provide adequate analgesia. They should attempt to identify and address underlying conditions leading to agitation and delirium.	**Case 56-4 (Questions 1, 2)** **Case 56-5 (Question 1)** **Case 56-6 (Question 1), Table 56-1**
2	Opioids are the most commonly used analgesics in the ICU. Patient-specific characteristics and differences between hydromorphone, fentanyl, and morphine should be considered when designing the optimal analgesic regimen for a patient.	**Case 56-4 (Question 3), Table 56-2**
3	Sedative agents may be utilized in some patients who remain agitated after reversible causes of agitation are thoroughly addressed. Propofol and dexmedetomidine are recommended the first-line sedatives in most patients	**Case 56-5 (Question 2), Table 56-3**

	and should be titrated to achieve light sedation.	
4	Clinicians can reduce the incidence of delirium by minimizing patients' exposure to risk factors for delirium and by implementing early mobilization protocols.	**Case 56-6 (Question 2)**
	STRESS ULCER PROPHYLAXIS IN THE INTENSIVE CARE UNIT	
1	Stress-related mucosal damage can lead to occult gastrointestinal (GI) bleeding in high-risk critically ill patients. All ICU high-risk patients should be evaluated to determine the appropriateness of pharmacologic stress ulcer prophylaxis (SUP).	**Case 56-7 (Questions 1–3)**
	GLYCEMIC CONTROL IN THE INTENSIVE CARE UNIT	
1	Both hypoglycemia and hyperglycemia result in negative outcomes for critically ill patients. Generally, clinicians should target a blood glucose concentration of 140 to 180 mg/dL utilizing insulin to manage hyperglycemia. Ranges of 110 to 140 mg/dL may be appropriate for some patients.	**Case 56-8 (Question 1)**

INTRODUCTION

Patients who are admitted to the intensive care unit (ICU) require close monitoring, given their potential severity of illness or risk of

decompensation. Many different types of ICUs exist, which are often focused on a certain type of organ dysfunction or familiarity with certain procedures or monitoring. Often, these ICUs are quite interdisciplinary in nature, relying on the expertise of many to improve the care of the patient. Evidence-based medicine in the critical care setting is often limited, requiring the synthesis of multiple types of literature as well as clinical experience to determine medication choice, route, dosing, and monitoring.

In this chapter, foundations of medication therapy for the critically ill patient are reviewed, including considerations for continuing home medications, and medication therapies that may improve clinical outcomes, such as sedation and analgesia, stress ulcer prophylaxis (SUP), and glycemic therapies for glucose control.

HOME MEDICATIONS IN THE INTENSIVE CARE UNIT

The management of home medications in an ICU can be a very challenging aspect of care for the medical team. Medication reconciliation has become an increased priority for hospitals, and pharmacists play a vital role. One study found that 36% of patients admitted to the hospital had at least one medication error, and 85% originated from the patient's medication history.[1] Often, the ideal method of obtaining a home medication list is through information obtained in a patient interview. However, this can be difficult in an ICU because many patients are intubated, sedated, delirious, and/or unable to participate in a patient interview. Thus, other methods are required, including interviewing family or friends, calling community pharmacies, locating outside medical records, or looking at previous hospital admissions. Medication reconciliation was shown to decrease discharge medication errors from 57% to 33% on a medical unit and from 80% to 47% on a surgical unit.[2] The importance of restarting home medications in the ICU varies among

different agents and medication classes. Multiple types of adult ICUs exist in the United States, including medical, surgical, burn, and neurosurgical. This section limits discussion to surgical and nonsurgical ICUs and the role of home medications for common situations in these ICUs. In addition, transitions of care from the ICU, with the potential impact of post-intensive care syndrome (PICS) are discussed.

Patients in the ICU can be very complex by definition, and it can be difficult to ensure all important aspects of critical care are addressed daily. To enhance patient care and safety, the medical field has started to incorporate an effective tool borrowed from the airline industry: the checklist. One of the most widely used ICU checklists worldwide is FAST HUG, which stands for **F**eeding, **A**nalgesia, **S**edation, **T**hromboembolic prophylaxis, **H**ead of bed elevation, stress **U**lcer prophylaxis, and **G**lycemic control.[3] These are issues that should be addressed daily because of their impact on morbidity, mortality, and length of ICU stay. Clinical pharmacists working in an ICU have the option to use a personal checklist or other available checklists, including a modified version of FAST HUG, FASTHUG-MAIDENS. This acronym adds **M**edication reconciliation, **A**ntibiotics, **I**ndications for medications, drug **D**osing, **E**lectrolytes, **N**o drug interactions, allergies, duplications, or side effects, and **S**top dates (of medications) to FAST HUG.[4] These are checklists that could be used in any ICU; however, each pharmacist needs to find what works best for them to ensure optimal medical care for their service and patients.

CASE 56-1

QUESTION 1: S.M. is a 62-year-old male who comes to the ICU with an upper gastrointestinal (GI) bleed. He reports a 2-week history of poor oral intake and weight loss. For the past 2 days, he has had several episodes of bloody stools and presented to his local clinic today with the following vitals: 90/51 mm Hg, heart rate (HR) 110 beats/minute, and temperature 97.16 °F (36.2 °C). He is brought immediately to the emergency department (ED) where the following labs are obtained: hematocrit (Hct) 17%, white blood cell count (WBC) 8.2 × 10^9/L, international normalized ratio (INR) 5.2, Na 128 mEq/L, K 3.1 mEq/L, and

serum creatinine (SCr) 1.9 mg/dL. His current home medications are aspirin 81 mg by mouth daily, clopidogrel 75 mg by mouth daily, atorvastatin 40 mg by mouth daily, metoprolol XL 50 mg by mouth daily, lisinopril 10 mg by mouth daily, and warfarin 7.5 mg by mouth daily. The patient is immediately transfused with 2 units of red blood cells and is brought to the ICU.

Which of his home medications should be held after he is admitted to the ICU?

Nonsurgical Intensive Care Unit Patients

For the nonsurgical ICU patient, the indication for admission is a major determinant in what medications can be restarted. Often, medical ICU patients come in with hemodynamic instability, reduced left ventricular ejection fraction, and/or alterations in renal or hepatic function, which significantly alter baseline pharmacokinetics. These patients must be evaluated on a case-by-case basis to determine whether home medications should be restarted. Patients are admitted to the ICU because they need frequent monitoring and are in constant need of reevaluation. The medical team must consider that withdrawal can manifest from discontinuation of chronic home medications (eg, β-blockers, baclofen) or from discontinuation of other illicit substances (eg, heroin, cocaine, methamphetamine). Obtaining a thorough patient history may help prevent medication withdrawal; however, because of the frequent inability to obtain a medical history, the ICU team must determine whether withdrawal treatment is appropriate based on vital signs and physical examination. This section discusses home medications and how they should be addressed in common scenarios encountered in ICU patients.

Hemodynamic instability is one of the most common issues encountered in ICUs. The causes of hypotension include hypovolemia, heart failure, and infection. Knowing the patient's baseline blood pressure can help determine the seriousness of the hypotension. A drop in baseline blood pressure can result in hypoperfusion and in the development of shock. If a patient cannot maintain adequate blood pressure, vasoactive medications (eg,

epinephrine, norepinephrine, phenylephrine, vasopressin) may need to be initiated. Common indicators of lack of perfusion are monitored in the ICU, including cool skin, metabolic acidosis, change in mental status, elevated serum lactate levels, and reduced urine output. If a patient comes to the ICU with hypotension and signs of hypoperfusion, home blood pressure medications of all classes should be held until there is a resolution of the underlying cause of the hypotension and hypoperfusion. Blood pressure medications should be slowly added back at reduced doses to the patient's hospital medication regimen.

Severe cases of hypertension in the ICU must be dealt with urgently to prevent stroke and/or end-organ damage. Common causes of hypertension in the ICU are missed hemodialysis, medication nonadherence, volume overload, and pain. The differential of high blood pressure is extensive, so determining the cause will help determine the direction of treatment. Hypertensive emergencies, defined as a large elevation of systolic blood pressure (SBP >180 mm Hg) or diastolic blood pressure (DBP >120 mm Hg) along with target-organ damage, need to be treated immediately because of possible complications, including cerebral infarction, intracranial hemorrhage, aortic dissection, and renal failure.[5] Intravenous (IV) medications are often required to control blood pressure in the ED or during the early hours of ICU admission. Common medications used are esmolol, diltiazem, hydralazine, labetalol, and nicardipine. These medications work immediately and can be titrated to lower blood pressures to the desired targets. IV medications are used in the short term until chronic antihypertensives can be administered and titrated. Restarting home blood pressure medications in the ICU is important unless there is a contraindication (ie, new renal dysfunction) or the patient now has a new condition that warrants a change in medication class (ie, β-blockers and angiotensin-converting enzyme inhibitor [ACEI] for new heart failure). This topic is discussed further in Chapter 16, Hypertensive Crises.

Because renal function is often unpredictable and unstable in the ICU, many classes of medications are withheld in the ICU. Renal

function can change very quickly in the ICU, and classic indicators of renal function such as SCr, which is used in creatinine clearance equations such as Cockcroft–Gault (CG) equation and the simplified four-variable Modification of Diet in Renal Disease (MDRD) equation, are delayed in acute renal failure or falsely low in the elderly. For this reason, drugs that can be evaluated using therapeutic drug monitoring (eg, vancomycin) should be monitored frequently. Other indicators including urine output, blood pressure, and volume status should be factored into determining an appropriate dosing for medications that are eliminated through the kidney. All medications administered in the hospital setting should be monitored daily and adjusted based on renal function.

Diabetes medications can cause complications in the ICU. Metformin can cause a metabolic acidosis if given to patients with renal dysfunction and is withheld in most ICU patients. Sulfonylureas are also withheld because of the frequent changes in diet in the ICU, which can result in hypoglycemia. As a substitute to prevent hyperglycemia, most patients are converted to a short-acting sliding scale insulin regimen, which accounts for poor oral intake or the withholding of nutrition at certain points in an ICU stay. Sliding scale insulin regimens give varying doses of insulin based on a patient's most recent glucose level. Basal insulin can be considered for patients diagnosed with diabetes, who are not receiving adequate control from sliding scale insulin.

Pain and medications used to treat pain are discussed in various chapters in this textbook (see Chapter 55, Pain and Its Management, for more details). For a new ICU patient, knowing a patient's home medication pain regimen can be very helpful and often vital to good patient care. A patient on chronic opioids should be continued on a pain regimen that includes opioids unless there is a contraindication to do so. Often, the regimen must be modified to account for renal function and route of administration. For example, many of the long-acting formulations cannot be crushed and put down a feeding tube, and a patient with renal dysfunction may need a lower dose or accounting for potential active metabolite accumulations with certain opioids (eg, morphine).

The dynamic nature of the ICU can make anticoagulation a very challenging issue. Unless the patient will likely be in the ICU for a short period of time, vitamin K antagonists (eg, warfarin) or the direct oral anticoagulants (eg, apixaban, dabigatran, rivaroxaban) will often be held in the ICU to prevent complications surrounding procedures and the altered pharmacokinetics in ICU patients. A detailed patient history is essential to determine the indication for anticoagulation. This will help the medical team determine if full anticoagulation should be continued. The discussion to continue anticoagulation will be determined on a case-by-case basis after weighing the risks and benefits of anticoagulation and often discussing the issue with consult services, such as cardiology, vascular surgery, and the primary care team. If full anticoagulation is required in the ICU, unfractionated heparin (UFH) may be the best option, because it can be more readily stopped and reversed if needed, compared to other agents. Almost all patients in the ICU are at increased risk for a venous thromboembolism (VTE) because of the lack of mobility, older age (70 years or older), heart failure, respiratory failure, previous VTE, acute infection, obesity, and/or ongoing hormonal treatment. Because of increased risk for VTE, patients should be placed on anticoagulant thromboprophylaxis with low-molecular-weight heparin (LMWH) daily or two times daily (bid), low-dose unfractionated heparin (LDUH) bid or three times daily (tid), or fondaparinux unless a contraindication exists.[6]

One of the biggest complications for a pharmacist in an ICU patient is finding an ideal medication regimen for a patient who cannot take any medications by mouth or who have a feeding tube. For patients who have a feeding tube, medications can be given down the feeding tube in certain circumstances. The pharmacist must determine which home medications can be crushed or come in a solution or liquid form. Often, long-acting medications must be converted to immediate release, or the medication must be changed so it can be crushed to go down a feeding tube. The Institute for Safe Medication Practices (ISMP) has created a resource for medications that cannot be crushed: http://www.ismp.org/tools/donotcrush.pdf. Certain patients in the ICU

will be ordered to not receive anything by mouth, including medications. It should always be clarified with the medical teams whether an NPO or "nothing by mouth" order includes medications. Many circumstances allow for the patient to receive oral medications on an NPO order. If medications cannot be given by mouth or there are concerns about absorption in the GI tract, the ICU teams will request that medications be converted from oral to IV form, if possible. Although some medications have IV formulations, many do not. A clinical pharmacist can assist with dosage conversions, frequency of administration, and alternative options for medications that do not have IV equivalents.

Owing to the fact that S.M. is actively bleeding, all anticoagulant and antiplatelet medications should be held. S.M. should have his aspirin, clopidogrel, and warfarin held. In addition, because he has an elevated INR, he should receive vitamin K to reverse the effect of warfarin. Once his bleeding has stopped, the team will have to determine which medications can be restarted and at what time the medications can be restarted.

Surgical Patients

CASE 56-2

Question 1: D.H. is a 68-year-old with a past medical history (PMH) of coronary artery disease (CAD) (drug-eluting stent placed 11 months ago), diabetes, and atrial fibrillation, who will be undergoing a knee replacement procedure in 1 week. His home medications on arrival to the hospital today include aspirin 81 mg by mouth daily, clopidogrel 75 mg by mouth daily, metoprolol XL 100 mg by mouth daily, and metformin 1000 mg by mouth bid. All his labs are within normal limits on the day of arrival.

The surgery team wants your advice: what medications should be continued throughout surgery, and what medications should be stopped?

Consequences of stopping a chronic medication before, or failing to restart that medication after surgery, can be significant. For example, abrupt discontinuation of a β-blocker during the perioperative period in a patient who has been on chronic β-blocker

therapy can increase the risk of death in the intraoperative and postoperative period. The American College of Cardiology/American Heart Association (ACC/AHA) recommends continuation of β-blocker therapy in patients undergoing surgery who are on a β-blocker chronically.[7] The use of ACEIs and angiotensin-receptor blockers (ARBs) may increase the risk of hypotension after induction of anesthesia when these agents are not withheld 24 hours before surgery.[8] Stopping the ACEI before surgery, however, can result in adverse postoperative effects, such as rebound hypertension and atrial fibrillation. Therefore, the decision to continue or stop before surgery is made on an individual basis, taking into consideration the indication and the type of surgery.[7] Medications such as amiodarone, calcium-channel blockers, clonidine, digoxin, and statins should be continued. Preoperative withdrawal of a statin in a patient undergoing major vascular surgery, for example, increases the risk of myocardial infarction and cardiovascular death after surgery.[7] Diuretics are typically held the morning of surgery to minimize the risk of hypovolemia and electrolyte abnormalities.

Oral antidiabetic agents and noninsulin injectable agents are typically held the morning of surgery and not restarted until normal food intake resumes. In patients with renal dysfunction and those who may receive IV contrast media, metformin should be discontinued 24 to 48 hours before surgery to reduce the risk of perioperative lactic acidosis. For patients on insulin therapy, a portion of the morning dose of intermediate- or long-acting insulin is generally administered on the day of surgery after a check of the patient's blood glucose. Close blood glucose monitoring guides subsequent insulin doses to avoid hypoglycemia.[9]

Antiepileptics, antipsychotics, benzodiazepines, lithium, selective serotonin reuptake inhibitors (SSRIs) and serotonin norepinephrine reuptake inhibitors (SNRIs), tricyclic antidepressants (TCAs), and carbidopa/levodopa has a higher risk for withdrawal or disease decompensation than for perioperative complications. These medications should, therefore, be continued up to and including the morning of surgery.

Nonselective nonsteroidal anti-inflammatory drugs (NSAIDs) reversibly inhibit platelet aggregation and are often stopped 1 to 3 days before surgery, depending on the duration of action of the drug. Celecoxib does not affect platelet aggregation and may be continued up to and including the day of surgery. Nonselective NSAIDs and celecoxib should be held if there is a concern for impaired renal function during or after surgery.

For patients on anticoagulant or antiplatelet therapy, the risks for thromboembolism must be balanced with the risk for bleeding during and after the surgical procedure. For patients on warfarin who are at high risk for perioperative thromboembolism, bridging anticoagulation therapy with IV heparin or LMWH before surgery may be recommended, depending on the underlying indication. Warfarin may not need to be discontinued if the patient is undergoing minor surgery (eg, certain dental, dermatologic, or ophthalmic procedures). For patients who have had coronary stents recently placed, discontinuing antiplatelet therapy prematurely can significantly increase the risk of perioperative stent thrombosis and have catastrophic consequences.[10] The 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery: Executive Summary recommends that patients undergoing urgent noncardiac surgery during the first 4 to 6 weeks after receiving a bare metal stent or drug-eluding stent implantation should continue dual-antiplatelet therapy (aspirin plus P2Y12 platelet receptor inhibitor) unless the relative risk of bleeding outweighs the benefit of the prevention of stent thrombosis.[7] They also recommend that the management of perioperative antiplatelet therapy be determined by a consensus of the surgeon, anesthesiologist, cardiologist, and patient, who should weigh the relative risk of bleeding with those of prevention of stent thrombosis.

Traditionally, it was thought that patients who have been taking long-term corticosteroid therapy before surgery will experience adrenal insufficiency in the perioperative period and should receive a supplemental stress dose of hydrocortisone or methylprednisolone during and up to 2 to 3 days after surgery.[11] A review of the literature,

however, found that patients on long-term corticosteroid therapy only require continuation of their normal daily dose of corticosteroid in the perioperative period.[12] These patients are generally able to increase their endogenous adrenal function above their baseline corticosteroid dose to meet the increased demand from surgery; a supplemental stress dose of corticosteroid is not necessary. These patients can be closely monitored, and if hypotension develops, a stress dose of a corticosteroid should be administered at that time. Patients who have a known dysfunctional hypothalamic–pituitary–adrenal axis deficiency (eg, Addison disease), on the other hand, will require supplemental corticosteroid doses in the perioperative period as they cannot increase endogenous cortisol production to meet the increased demand from surgery.[12]

Patient on chronic opioids who undergo surgery often experience more severe acute pain after surgery. These patients should receive either their chronic opioid medication or a comparable dose of an IV opioid the morning of surgery to meet their daily requirements to avoid uncontrolled pain and opioid-withdrawal symptoms. The use of nonopioid analgesics or analgesic techniques (eg, acetaminophen, epidural analgesia, peripheral nerve blockade) for perioperative analgesia should be maximized in a postoperative patient.[13]

For D.H., because his stent is over 6 weeks old, his clopidogrel should be held 5 to 7 days before surgery. His warfarin should also be held 5 to 7 days before surgery and likely does not need bridging with an UFH or LMWH. His aspirin can be continued through surgery.

Transitions of Care/Post-Intensive Care Syndrome

The transition of a patient from the ICU to another clinical setting, such as the general ward, skilled nursing facility, or even home, should be seen as an opportunity to closely evaluate the appropriateness of a patient's medication therapies. This often includes not only medications that were initiated in the ICU setting

but also a patient's home medications that were held during their ICU stay. Studies have shown that antipsychotics (more details in "Pain, Agitation, and Delirium in the Intensive Care Unit" section), a class of medications that may be prescribed for the management of agitation and/or delirium in the ICU, are often continued upon transfer to the general ward and even upon hospital discharge, with rates of 26% and 21%, respectively.[14,15] The continuation of these therapies may result in this becoming an inappropriately prescribed chronic medication, along with the potential adverse chronic effects associated with antipsychotics. Midodrine, an α_1-agonist used for increasing blood pressure, has been shown to be continued at discharge in 34% of patients who were newly prescribed it in the ICU.[16] Finally, a multicenter study of medication errors focusing on transition from the ICU to a non-ICU setting found that ~45% of patients had at least one medication error present during transitions of care.[17] These studies underscore the importance of ensuring that an adequate pass-off of a therapeutic plan for medications started in the ICU is completed before transfer to another setting.

One important aspect of transitions of care is PICS, which is an increasingly studied phenomenon that occurs in patients who survive their ICU stay. This term was first described in 2012 and is associated with cognitive impairment, altered ability to participate in activities of daily living, as well as mental health impairment.[18] This may persist for months to years after ICU discharge and is estimated to occur (in various degrees) in up to 60% of ICU survivors.[19] One innovation that has attempted to mitigate the effects of PICS is interdisciplinary clinic, often including a pharmacist, which helps to support ICU survivors, which includes identifying signs and symptoms of PICS. One study of pharmacist involvement in a PICS clinic found a median number of four interventions per patient, which included medication discontinuation in 39% of patients and the identification of adverse drug events in 16% of patients.[20] Pharmacist involvement in this arena can be another method to decrease patient morbidity associated with transitions of care.

PHARMACOKINETIC ALTERATIONS IN THE INTENSIVE CARE UNIT AND MANAGEMENT STRATEGIES

Pharmacokinetics in the Critically Ill

The dynamic nature of critical illness may cause drastic changes in the pharmacokinetic profile of many medications. Before describing these changes, it is important to first consider where the majority of available pharmacokinetic data are generated.

As a medication makes its way through the discovery process, pharmacokinetic data are obtained in phase I trials and in noncritically ill patients. Phase 1 trials in humans are most commonly done in healthy subjects in highly controlled environments. When pharmacokinetic data are obtained in phase II/III trials, critically ill patients are excluded. As a result, errors may arise in assuming that patients with the disease of interest and, more importantly, critically ill patients have similar pharmacokinetic parameters. Although available pharmacokinetic data should always be consulted in formulating a therapeutic regimen, the pharmacist should be attuned to the limitations inherent in the data.

CASE 56-3

QUESTION 1: J.K. is a 67-year-old male who presents to the ICU with a 3-day history of cough and shortness of breath. J.K. is diagnosed with severe sepsis owing to pneumonia and is intubated on admission to the ICU. J.K. is started on broad-spectrum IV antibiotics, including piperacillin–tazobactam and vancomycin. After receiving 6 L of lactated ringers, J.K. remains hypotensive, and a norepinephrine infusion is initiated to maintain his mean arterial pressure >65 mm Hg. J.K. is placed on enoxaparin 40 mg subcutaneously daily and pantoprazole IV daily for deep venous thromboembolism (DVT) and SUP, respectively. On day 3 of his ICU course, J.K. develops acute kidney injury (AKI) secondary to sepsis/hypoperfusion, with his SCr rising from a baseline of 1.1 to 3.4 mg/dL. J.K. has a nasogastric (NG) tube placed for enteral nutrition. On day 6 of his ICU stay, J.K. develops a severe *Clostridioides difficile* colitis for which oral vancomycin is initiated.

What are potential abnormalities of medication absorption in J.K.?

With the exception of IV administration, all medications must undergo absorption in order to reach the systemic circulation. Bioavailability (F) is defined as the percentage of the administered dose that reaches the systemic circulation.

Gut function may be altered in J.K. for a variety of reasons, including delayed gastric emptying, ischemic bowel, inflammation, and coadministration of interacting substances. Each of these issues may lead to significant delays and/or decreases in the amount of orally/enterally administered medication absorption.

Delayed gastric emptying is a common occurrence in the ICU patient population, occurring in 40% to 60% of patients.[21] It may be caused by many factors, including postoperative ileus, trauma, head injury, sepsis, burns, or opioid use.[22] Delayed gastric emptying would be evident in J.K. if he was manifesting high gastric residual volumes or enteral feeding intolerance. Because most medications are absorbed in the small intestine, delayed emptying would most likely affect the rate of absorption, slowing the onset of action of medications in J.K.

Ischemic bowel may also cause J.K. to have alterations in his ability to absorb oral/enteral medications depending on what portion and how much of the bowel is affected. In J.K., ischemic bowel may be caused by vasopressor use and/or the presence of a shock state. Because drug absorption occurs primarily in the small bowel, impaired blood flow to this area would be more likely to decrease the extent of absorption of medications.

Acute gut inflammation may increase the absorption of certain medications in J.K. With the development of severe clostridium colitis on day 6, J.K. may experience increased oral absorption of oral vancomycin. Under normal patient conditions, oral vancomycin is not orally absorbed because of the ionization and large size of the molecule. There have been several reports of therapeutic plasma levels of vancomycin being achieved with oral treatment of severe *C. difficile* infections.[23–26] The postulated mechanism is the severe

inflammation in the colon allowing for the passage of larger, charged molecules into the bloodstream.

Orally administered medications are not the only route that may have altered absorption in the ICU. Subcutaneous absorption has also been shown to be remarkably altered in ICU patients, particularly those on vasopressor therapy. It is postulated that vasopressor treatment causes a decrease in subcutaneous tissue perfusion, resulting in impaired absorption of subcutaneously administered medications. Studies have shown that patients on LMWH therapy also receiving vasoconstrictive agents have markedly reduced peak and total anti-Xa activity when compared to other hospitalized patients.[27–30]

Case 56-3, Question 2: How should absorption issues in J.K. be managed?

Generally speaking, when there is a question of gut function in the ICU, IV formulations are preferred when available. In cases where a given medication would produce an objective response (eg, antihypertensive, hypoglycemic agents), enteral therapy may be attempted to assess patients' response. The pharmacist should be attuned to the specific pharmacodynamic response of a given medication to assess therapeutic response with oral/enteral dosing.

In the case of J.K., consideration may be given to monitoring anti-factor Xa levels for enoxaparin, while he remains on vasopressor therapy. Trough levels of <0.1 IU/mL have been associated with increased risk of the development of DVT.[29] In addition, if J.K. is deemed suitable for enteral medication therapy, his proton-pump inhibitor (PPI) therapy could be changed to a dissolvable (solu-tab) formulation, which generally is preferred to crushing and dissolving oral tablets to prevent obstructing tubes and for ease of administration. Consideration could also be given to monitoring serum vancomycin concentrations more aggressively, because J.K. may be at risk for significant vancomycin absorption given his severe *C. difficile* infection while also receiving systemic vancomycin therapy.

Case 56-3, Question 3: What are the potential changes in the distribution of a medication in J.K.?

The distribution of a medication is defined briefly as where the drug goes once it is absorbed into the bloodstream. The extent of distribution of a medication is dependent on both physiochemical drug properties and patient-specific factors. The physiochemical properties of a drug that determine how extensively it distributes to tissues include lipophilicity and protein binding, with high lipophilicity leading to extensive tissue distribution, and lower protein binding contributing to more extensive distribution. Patient-specific factors that determine the distribution of a medication include weight, volume status, and vascular permeability.

J.K. has a multitude of factors that may affect the distribution of hydrophilic (ie, low volume of distribution) medications, including the presence of sepsis and large volume of crystalloid (eg, normal saline) administration. These conditions result in decreased plasma concentrations of hydrophilic medications, leading to potentially subtherapeutic concentrations.[31]

Patients who have sepsis may possess several factors that would lead to a decreased plasma concentration of hydrophilic medications, including the presence of capillary leak (ie, third spacing), causing intravascular fluid to distribute to tissues, the administration of large volumes of IV crystalloid medications, and reduced tissue perfusion. This is particularly well-documented with antibiotic therapy in this patient population. Most infections occur in the interstitial fluid of tissues; thus, interstitial antibiotic concentrations would be most relevant to determine efficacy. Studies have shown that the interstitial fluid concentration and subcutaneous concentration of antibiotics is 5 to 10 times lower and 1 to 5 times lower, respectively, in septic patients as compared to normal controls.[32]

Septic ICU patients may also have drastic changes in plasma protein (eg, albumin) concentration because of reduced liver production and third spacing of albumin into tissue sites. Low plasma

protein will cause an increase in the unbound fraction of drug, increasing distribution to tissues. Unfortunately, this increased distribution is more than offset by the increase in fluid concentration secondary to capillary leak and volume administration of the interstitial tissues, causing low concentrations of antibiotics in interstitial fluid.

Understanding that the distribution of hydrophilic antibiotics (piperacillin/tazobactam, vancomycin) is likely increased in J.K., several strategies can be employed to offset these changes. Interventions include giving more frequent doses or continuous infusions with β-lactam therapy and using large initial doses (30–40 mg/kg/day) of vancomycin in conjunction with targeting trough levels of 15 to 20 mg/L.[32]

CASE 56-3, QUESTION 4: What are the potential alterations in metabolism in J.K.?

Drug metabolism can occur in a variety of body tissues, including the kidneys, GI tract, lung, and liver. The liver is the predominant metabolizing organ and is the focus of this section. Patients in the ICU may have alterations in hepatic enzyme activity, liver blood flow, and protein binding, all of which may influence the rate at which hepatically metabolized medications are biotransformed.

Liver metabolism is broken into two major categories, phase I and phase II metabolism, both of which transform drugs into more polar substances that are more readily excreted. Phase I metabolism refers to the cytochrome P450 (CYP) enzyme system that works through oxidation, reduction, and hydrolysis. Phase II metabolism, in contrast, adds large polar molecules to the parent compound, including glucuronidation, sulfation, and acetylation.

There may be significant factors that alter phase I metabolism in J.K., including kidney injury, inflammation, and hypothermia.

Renal dysfunction can reduce phase I metabolism through reduced hepatic cell uptake of medications and reduced biliary excretion.[33,34] The inflammatory response secondary to trauma has

shown variable effects on enzymatic activity, with reduction in CYP3A4, CYP2C19, and CYP2E1 and with increased CYP2C9 activity.

Therapeutic hypothermia has been well-documented to reduce CYP activity across all isoenzyme families. This is especially well-documented with medications commonly given to ICU patients, including neuromuscular blockers, fentanyl, phenytoin, and midazolam. It is important to consider that enzyme activity recovers during the rewarming process, necessitating close monitoring and potential dose adjustment.[29]

Hepatic blood flow (ie, perfusion) may also be altered in J.K. Reductions in hepatic blood flow because of hypotension (eg, shock) or shunting (eg, cirrhosis) may have significant effects on prolonging the half-life of medications that are dependent on liver blood flow for metabolism. These medications are defined as having a high hepatic extraction ratio ($E > 0.7$) and would include medications such as midazolam and fentanyl.[22]

Protein-binding alterations may also occur in the critically ill and may subsequently affect the metabolism of select medications. Specifically, albumin concentrations may acutely decrease, thus increasing the free fraction of medications that are normally bound. This is especially relevant for medications that have high extraction ratios, as more medication would be available for removal, causing a net reduction in drug half-life.

Case 56-3, Question 5: How should metabolism issues be managed in J.K.?

To properly manage metabolism alterations in the ICU, the pharmacist should first be aware of the patient populations who are most likely to have altered metabolic rates/pathways, including renal dysfunction, burns, therapeutic hypothermia, and decreased hepatic perfusion. In addition to identifying at-risk patients, the pharmacist should be aware of those medications that are most likely to have altered metabolism. These would include medications metabolized through the CYP system as well as those with high extraction ratios

(E > 0.7). Increased vigilance in monitoring for therapeutic effect/toxicity with these medications in at-risk patients is warranted.[22,35]

CASE 56-3, QUESTION 6: How is elimination altered in J.K.?

Elimination is the process by which a drug or its metabolites are removed from the body. Although the kidney is the main organ that eliminates medications, it is important to remember that there are other organs (liver/lung) that also may contribute to elimination.[22] In addition, there exist several therapeutic interventions that occur in the ICU that also contribute to medication elimination, including continuous renal replacement therapy (CRRT) and extracorporeal membrane oxygenation (ECMO).[36]

Glomerular filtration is the primary method of renal clearance of medications, and renal drug removal is usually directly proportional to glomerular filtration rate (GFR). AKI is a common comorbidity in the ICU population, occurring in 1% to 25% of patients, leading directly to reduced medication elimination.[22] Other factors may increase the GFR in ICU patients, including trauma, burns, and use of vasopressors.

Renal function assessment is critical to appropriately dose adjusting renally eliminated medications and proves to be difficult, especially in the ICU population. The SCr measurement often lags behind actual GFR, because there exist changes in creatinine production and altered tubular secretion. In addition, most estimates of renal function, including the CG equation and the MDRD equation, were validated only in patients with stable renal function.[37,38] Attempting to apply these equations to a patient with fluctuating SCr measurements will result in inaccurate estimations of renal clearance.

In addition to renal function, there exist other modalities that contribute to drug elimination in specific ICU populations, including CRRT and ECMO. Although a detailed description of these processes is beyond the scope of this chapter, the clinician should

remember that both may remove medications in clinically relevant quantities.

It is also important that the pharmacist consider not only the elimination of the parent compound but also the presence of active/toxic metabolites that require renal elimination. Examples of medications with clinically significant toxic metabolites are nitroprusside and meperidine.[39,40] Renal dysfunction may lead to accumulation of toxic metabolites, causing patient harm. Common medications given in the ICU with active metabolites are midazolam and diazepam. These active metabolites may accumulate in renal insufficiency and cause exaggerated/prolonged sedation/delirium.[41,42]

CASE 56-3, QUESTION 7: How should elimination alterations be managed in J.K.?

Estimation of renal function is critical to appropriately dosing many medications in the ICU. As discussed earlier, using the usual process of calculating renal function is often inaccurate, and typical equations (eg, CG/MDRD) should only be used in patients with stable SCr values. In patients with unstable SCr values, consideration should be given to calculating creatinine clearance using a 24-hour urine collection. Other data points should also be considered when determining an appropriate dose in critical illness and include urine output, trends in SCr, and the specific medication to be dosed. For J.K., this would mean frequent monitoring of vancomycin serum concentrations, anti-Xa monitoring for enoxaparin, and daily assessment of SCr and urine output trends. In addition, medications with active metabolites requiring renal elimination (eg, midazolam) should be avoided if possible.

Pain, Agitation, and Delirium in the Intensive Care Unit

Pain, agitation, and delirium commonly occur in critically ill patients for a variety of reasons. Invasive interventions such as intubation and mechanical ventilation, acute and preexisting disease states, and surgery are just a few of the common causes of pain in critically ill patients.[43,44] Patients may become agitated and develop delirium because of untreated or inadequately treated pain or because of many other reasons, including substance use disorder or withdrawal, adverse effects of medications, sleep deprivation, and the impact of comorbidities or severe illness.[43,44] Pain, agitation, and delirium are interrelated, and it is often difficult to differentiate these conditions based on symptoms in patients who are severely ill and often unable to communicate. They require prompt and effective interventions because they can lead to patient discomfort, heightened sympathomimetic activity, and negative patient outcomes. Clinicians should judiciously balance management of pain, agitation, and delirium in an effort to keep patients lucid, calm, interactive, free of pain, and cooperative with their care.[45]

CASE 56-4

Question 1: J.A. is a 28-year-old male who presents to the ED after a severe motor vehicle accident. He presents with hemorrhagic shock, multiple rib and leg bone fractures, and a traumatic brain injury. He is immediately intubated and taken to the operating room for control of his bleeding and initial management of his fractures. His PMH is significant for opioid use disorder and bipolar disorder. After the operation, J.A. is transferred to the surgical ICU on mechanical ventilation with multiple chest tubes in place for management of injuries he sustained in the accident.

What causes of pain does J.A. have, and what complications might they cause?

Up to 77% of patients discharged from ICUs report experiencing moderate or severe pain during their ICU stay.[46,47] This pain occurs during rest and with activity and is the most common memory patients have of their ICU stays.[48] Pain may occur because of injuries or diseases, therapeutic interventions, routine ICU care, or monitoring. Common causes of pain are listed in **Table 56-1**.

Patients consistently report pain as the most traumatic memory from their ICU stay.[49] During the ICU stay, untreated pain can result in increased energy requirements, hyperglycemia, muscle breakdown, immunosuppression, increased risk of wound infection, decreased tissue perfusion, psychological distress, and impaired sleep. Long-term complications of untreated pain include chronic pain syndromes, neuropathy, posttraumatic stress disorder, and a decreased health-related quality of life.[50] In light of the acute and long-lasting consequences of pain as well as the prevalence of untreated pain in critically ill patients, it is important to diligently assess patients and utilize appropriate analgesics when indicated.

Table 56-1
Common Causes of Pain in Critically Ill Patients

Injuries and Diseases	Interventions and Monitoring	Routine Care
Trauma	Endotracheal intubation	Turning
Burns	Endotracheal tube for mechanical ventilation	Suctioning of respiratory secretions
Pancreatitis	Chest tube placement	Physical therapy
Necrotizing fasciitis	Wound care	
Decubitus ulcers	Surgery	
Immobility	Vascular access (arterial catheter)	
Preexisting disease states (eg, cancer, chronic back pain)		

In J.A., the potential causes of pain include trauma, postoperative pain, and the presence of an endotracheal tube and chest tubes. During his ICU stay, he may experience pain from routine care, including turning, suctioning of respiratory secretions, and, eventually, physical therapy.

Case 56-4, Question 2: How should J.A. be assessed for pain in the ICU?

Because patient-reported pain assessment is the optimal way to assess pain, whenever possible, clinicians should ask patients to rate their pain on a scale from 0 to 10, with 0 representing no pain and 10 representing the worst pain imaginable. For patients who cannot communicate with caregivers because of mechanical ventilation or other limitations, clinicians should assess patients' pain scores using validated nonverbal pain assessment tools that utilize patient behaviors as indicators of pain. The two nonverbal pain assessment tools recommended in guidelines are the Behavioral Pain Scale and the Critical-Care Pain Observation Tool.[43,44] The maximum score on each tool is 12 and 8, respectively, with higher values indicating more severe pain. Pain assessment should be protocolized such that it routinely occurs throughout each day of the patient's ICU stay. Clinicians should set the goal pain level and utilize analgesics as needed to maintain patients at the goal score while considering potential adverse effects. Generally, hemodynamic parameters such as blood pressure, HR, and respiratory rate should not be used to assess pain because they can be affected by other factors and do not correlate with self-reported pain; however, changes in vital signs may be used as a cue to further assess patients.[43,44]

Case 56-4, Question 3: How should clinicians manage pain in critically ill patients like J.A.?

Opioids are the primary analgesics used in the critical care setting. Fentanyl, hydromorphone, and morphine are used most commonly, whereas methadone is mainly used for long-term pain or pain that is refractory to other opioids. Because it is very short acting, very potent, and metabolized in the plasma, remifentanil is most appropriate for pain that lasts only a short period of time in patients who are mechanically ventilated and in those with severe renal or hepatic dysfunction. Meperidine should not be used because it may cause seizures and other complications.[50] For the treatment of acute pain, opioids should be given IV because enteral administration may

be unreliable in critically ill patients because of incomplete absorption in patients with altered GI motility and intramuscular absorption can be erratic. Enteral opioids, including methadone, may be utilized when transitioning patients off of long-term analgesic infusions or treating chronic pain as patients transition to less acute levels of care. In some cases, it may be impossible to completely alleviate pain because of dose-limiting side effects, such as respiratory depression or altered mental status. In these cases, clinicians should attempt to make patients as comfortable as possible without inducing significant adverse effects.

The selection of a specific opioid relates to the pharmacokinetics and pharmacodynamics of the medications and depends on patient-specific characteristics as well as the nature of the pain the patient is experiencing. **Table 56-2** lists key considerations for choosing between available opioids. When given as a single IV bolus injection, fentanyl has a faster onset and shorter duration of action compared to hydromorphone and morphine. This makes an IV injection of fentanyl most appropriate for pain that is short-lived such as procedural pain that might be associated with placement of a chest tube or IV catheter. In fact, procedural pain is best treated preemptively through administration of a bolus agent before the procedure.[43,44] The longer duration of action of hydromorphone and morphine makes these agents better when IV bolus treatment of longer lasting pain is indicated. Alternatively, fentanyl, hydromorphone, and morphine may all be administered as continuous IV infusions in patients needing ongoing analgesia or in those with severe pain.

Table 56-2
Selected Characteristics of Opioids Used in Critically Ill Patients

	Onset	Duration (IV Bolus Dose)	Active Metabolite	Adverse Effects and Other Considerations	Equipotent IV Dose (mg)
Morphine	5–10 minutes	2–4 hours	Yes (cleared renally)	Histamine release (hypotension, bronchospasm, flushing)	10
Hydromorphone	5–15 minutes	2–4 hours	No		1.5
Fentanyl	1–2 minutes	30–60 minutes	No	Accumulates in adipose tissue with prolonged infusion	0.1

IV, intravenous.

All opioids can cause constipation, confusion, hallucinations, altered mental status, and respiratory depression when given in high doses. Clinicians should regularly monitor the bowel movements of patients receiving opioid analgesia and a bowel regimen containing both a stimulant laxative and a stool softener should be administered, if indicated. Opioids may cause a decrease in blood pressure if the patient's blood pressure is increased because of pain and in patients who are hypovolemic. Importantly, morphine is the most likely opioid to cause histamine release, which can lead to flushing, bronchospasm, and hypotension. These complications underlie the recommendation to avoid morphine in patients who are hemodynamically unstable, at risk for hypotension, or those with bronchospasm. Morphine is metabolized to an active metabolite that is cleared by the kidneys, whereas fentanyl and hydromorphone are metabolized in the liver to inactive metabolites. Thus, hydromorphone and fentanyl are preferred to morphine in patients with renal disease or injury. Another unique side effect relates to QTc prolongation resulting from methadone. Because QTc prolongation can potentially cause cardiac arrest, electrocardiograms should be regularly monitored in patients receiving methadone, especially when patients are concurrently receiving other QTc-prolonging agents. Serum concentrations of magnesium and potassium should be monitored, and these electrolytes should be repleted, as needed, to minimize arrhythmias. Because fentanyl is the most lipophilic of the most commonly used opioid analgesics, prolonged administration via IV infusion may lead to formation of a depot in adipose tissue. After cessation of the fentanyl infusion, the drug may distribute from the fat into the bloodstream and prolong the effects of drug.

In addition to opioids, clinicians may consider adjunctive analgesics in selected patients. For example, NSAIDs and acetaminophen may be considered to minimize overall opioid requirements and potentially reduce opioid-related complications. For patients experiencing neuropathic pain, enterally administered gabapentin, carbamazepine, and SNRIs can be helpful. For patients with rib fractures or those who have undergone thoracic or

abdominal surgery, thoracic epidural analgesia results in better pain control as compared to opioid monotherapy.[57] Select nonpharmacologic strategies such as music therapy and massage may help with pain in some patients.[43,44]

Because J.A. is likely to experience ongoing pain as a result of his trauma, multiple fractures, and surgery, he should be initiated on opioid analgesia. If he remains hypotensive, at risk for hemodynamic compromise, or is in renal failure, morphine should be avoided. Some centers would routinely use fentanyl or hydromorphone in most patients to minimize hemodynamic complications. It would be most appropriate to administer fentanyl as a continuous infusion, whereas hydromorphone could be given continuously or as repeated IV boluses. Because of his rib fractures, J.A. could also be considered for thoracic epidural analgesia with an opioid.

CASE 56-5

QUESTION 1: During his stay in the surgical ICU, J.A. begins to exhibit signs of agitation, including diaphoresis, tachycardia, pulling at his endotracheal tube, and even trying to strike his caregivers.

What are some causes of agitation that J.A. might be experiencing, and how should he be initially treated?

Agitation is very common in critically ill patients and can lead to adverse consequences arising from sympathomimetic effects.[51] Patient care can be complicated if agitation leads to patient removal of devices, such as endotracheal tubes or IV lines, necessary for their care. Patients may exhibit symptoms of agitation for a variety of reasons, including pain, delirium, hypoxemia, hypoglycemia, hypotension, or withdrawal from alcohol and other drugs. Given the ubiquity of pain in critically ill patients and the difficulty in assessing patients who cannot communicate, clinicians should always consider pain as a potential cause of agitation and administer analgesics when they suspect pain. In fact, current guidelines recommend analgesia-first sedation strategies that emphasize adequate use of analgesics before administration of sedative agents.[43,44] Other

general strategies to treat anxiety and agitation in critically ill patients include keeping patients as comfortable as possible, reorienting patients if they misperceive their surroundings or situations, and promoting a normal sleep–wake cycle by helping patients to stay awake during the day and minimizing barriers to sleep overnight. Whenever possible, clinicians should attempt to identify and treat the underlying cause of agitation before initiating a sedative agent. For instance, if an agitated patient is found to be hypoglycemic, the hypoglycemia should be corrected, and the patient should be reevaluated before starting a sedative. By identifying and addressing the cause of agitation, clinicians can avoid complications associated with sedative medications, such as oversedation and delirium.[43,44]

Clinicians should assess critically ill patients who are agitated using a validated sedation assessment tool.[43,44] The two most rigorously evaluated tools are the Richmond Agitation-Sedation Scale (RASS) and the Sedation-Agitation Scale (SAS). Both tools effectively discriminate the level of sedation, have high inter-rater reliability, and have been shown to correlate reasonably well with objective measures of brain function.[52–54] Score on the RASS ranges from −5 to +4, whereas the SAS score varies from 1 to 7. The lowest number of the scales indicates a patient is unarousable, whereas the highest number on the RASS and SAS corresponds to combativeness and dangerous agitation, respectively. By quantifying patients' level of sedation using one of these tools, multidisciplinary caregivers can determine the desired level of consciousness and appropriately administer medications to target this level of consciousness while avoiding excessive sedation. Generally, sedatives should be titrated to achieve light levels of sedation, which correspond to RASS scores of −1 to 0 and SAS scores of 3 to 4.[43,44] Maintaining patients at light levels of sedation instead of deeper levels of sedation, in which they are more difficult to arouse and are less interactive, has been shown to reduce duration of mechanical ventilation and ICU length of stay.[55,56] Sometimes, patients' clinical conditions may necessitate deeper levels of sedation. Some clinical situations in which deeper sedation may be appropriate include active severe alcohol withdrawal, refractory status epilepticus,

intracranial hypertension, ventilator dyssynchrony, severe acute respiratory distress syndrome, or paralysis with neuromuscular receptor blocking agents.

J.A. may be agitated because of pain from his traumatic injuries as well as metabolic disturbances or other causes. His level of consciousness should be evaluated using the RASS or the SAS. Because he is intubated, J.A. should be assessed for pain using a validated nonverbal pain assessment tool, and his pain should be treated if indicated. His vital signs should be evaluated to identify hypotension or hypoxia, and his blood glucose concentration should be measured. Abnormalities in these values should be corrected as needed. Clinicians should review J.A.'s PMH, social history, and home medication list to identify any potential that he might be experiencing withdrawal from alcohol, illicit substances, or prescribed medications that he was taking before hospital admission, such as benzodiazepines or opioids. If he is unaware of his surroundings or current condition, J.A. should be reoriented. His sleep pattern should be addressed. Finally, the patient's current medication list should be reviewed for medications, such as steroids and anticholinergic drugs, that might cause behavioral changes, and these medications should be discontinued if identified. Only after thoroughly assessing the patient for potentially reversible causes of agitation, should the health care team consider initiating a sedative medication with the goal of achieving a light level of sedation in J.A.

CASE 56-5, QUESTION 2: If J.A. requires sedation, which medication would be preferred?

Several agents, including propofol, dexmedetomidine, and benzodiazepines, can be used to treat agitation in critically ill patients. No one sedative is best for all patients. Although benzodiazepines have been widely used over time, propofol and dexmedetomidine are currently preferred in most patients because they may result in decreased ICU length of stay and duration of mechanical ventilation as compared to benzodiazepines.[43,44,57–59]

End points about the optimal sedative agent for individual patients depend on the reason for sedation and sedation goals, expected duration of sedation, pharmacology of the medication in the specific patient, and cost-effectiveness.[43,44] A summary of key clinical considerations relative to commonly used sedatives is provided in **Table 56-3**.

Table 56-3
Clinical Considerations With Sedative Agents

	Receptor-Binding Site	Onset (minutes)	Effect of Renal Failure	Effect of Hepatic Failure
Midazolam	$GABA_A$	2–5	Effect prolonged owing to accumulation of parent drug and active metabolite	Effect prolonged
Lorazepam	$GABA_A$	15–20	Accumulation of propylene glycol	Effect prolonged
Propofol	$GABA_A$, nicotinic, glycine, muscarinic	1–2	No clinically significant effect	No clinically significant effect
Dexmedetomidine	Central α-2	5–10	No clinically significant effect	Effect may be prolonged in severe hepatic failure

Propofol is a highly lipophilic sedative that binds to multiple receptors and exerts sedative, hypnotic, anxiolytic, antiemetic, and anticonvulsant properties. Because of its high lipophilicity and formulation in a 10% lipid emulsion, propofol readily crosses the blood–brain barrier and demonstrates a rapid onset of effect and quick offset after short-term use. However, patient awakening after prolonged use can be variable because of its deposition in adipose tissues.[60] Propofol can be rapidly titrated in order to achieve the desired level of sedation. It is suited for regular awakenings that are required for neurologic examinations in patients with brain injuries, and it facilitates daily awakening as part of sedative and ventilator weaning protocols.[59,61] Adverse effects of propofol include respiratory depression, hypotension resulting from vasodilation, bradycardia, hypertriglyceridemia, pancreatitis, myoclonus, and green or white discoloration of the urine.[62,63] Because of the dose-dependent suppression of respiratory drive, continuous infusions of propofol should only be administered to patients who are mechanically ventilated. Patients should be regularly monitored for hypertriglyceridemia when receiving propofol over the course of several days, and the drug should be stopped or weaned if significant hypertriglyceridemia develops. Patients with allergies to

eggs, soybeans, and sulfites may experience allergic reactions because of components of the lipid emulsion and some generic formulations.[64] In order to reduce burning and stinging associated with administration, propofol should be administered through large-bore IV lines whenever possible. Although propofol is formulated with a preservative to prevent bacterial growth, product labeling suggests the bottles and tubing should be changed every 12 hours, and line integrity should be assessed to prevent bacterial contamination. The caloric load of the lipid vehicle should be considered when evaluating nutritional needs in patients receiving propofol.

Propofol may cause a life-threatening syndrome called propofol infusion syndrome (PRIS) in about 1% of patients. PRIS is characterized by metabolic acidosis, hypertriglyceridemia, progressive hypotension, bradyarrhythmias, and cardiovascular collapse. Other complications of PRIS may include AKI, hyperkalemia, rhabdomyolysis, and liver failure.[65,66] PRIS has been observed most commonly at doses exceeding 70 μg/kg/minute and with use beyond 48 hours, but it has been reported at lower infusion rates and with shorter infusions.[67,68] Because PRIS can be difficult to distinguish from other conditions in critically ill patients and because of its high mortality rate, members of the health care team should diligently monitor patients in order to rapidly identify PRIS. When PRIS is suspected, propofol should be discontinued and patients should receive appropriate supportive care.[43,44]

Dexmedetomidine is a centrally acting α-receptor agonist that is similar to clonidine. It demonstrates greater anxiolytic and fewer sympatholytic properties as compared to clonidine. In addition to anxiolysis, dexmedetomidine also has sedative and opioid-sparing effects. It does not have anticonvulsive characteristics, induce amnesia, or cause respiratory depression.[43,44] Dexmedetomidine often allows patients to awaken more easily and better interact with caregivers as compared to propofol and benzodiazepines, but it is not appropriate for patients requiring deeper levels of sedation and those paralyzed with neuromuscular receptor antagonists.[69] Dexmedetomidine starts working within ~15 minutes after the

initiation of an infusion and reaches its peak effect at 1 hour.[70,71] Clinicians may administer a bolus to achieve faster onset, but bolus administration is associated with increased risk of hemodynamic instability, which can manifest as either hypertension or hypotension and bradycardia.[72] Additional adverse effects include nausea, atrial fibrillation, and, rarely, cardiogenic shock.[73] In the United States, dexmedetomidine is approved for use as a continuous infusion at doses up to 0.7 μg/kg/hour for a maximum of 24 hours, but clinical trials have demonstrated safety and effectiveness at doses up to 1.5 μg/kg/hour for as many as 28 days.[74–76] Doses may be titrated every 30 minutes. Patients with severe hepatic disease may require lower doses of dexmedetomidine to avoid prolonged offset of effect and excessive hemodynamic effects. Dexmedetomidine-induced hypotension and bradycardia may occur more commonly in patients who are hypovolemic or in those who have cardiovascular instability.[77] Importantly, because dexmedetomidine does not cause respiratory depression, it can be continued during and after extubation, unlike propofol.[77,78] When continuing dexmedetomidine in this manner, clinicians should be aware that it may cause loss of oropharyngeal muscle tone, resulting in airway obstruction. Consequently, patients getting dexmedetomidine without mechanical ventilation must receive continuous respiratory monitoring.

Benzodiazepines are γ-aminobutyric acid (GABA) receptor agonists that demonstrate anxiolytic, sedative, hypnotic, and anticonvulsant effects.[79] Current guidelines no longer recommend the use of benzodiazepines as the first-line sedatives in most critically ill patients, although they remain the mainstay of therapy for the management of alcohol withdrawal.[43,44] Benzodiazepines can potentiate respiratory failure and hypotension, especially when coadministered with opioids.[41] They can also cause mental status changes and are risk factors for the development of delirium.[76,80,81] Patients may occasionally experience a paradoxical reaction involving agitation and restlessness. Elderly patients are more likely to experience adverse effects, whereas patients taking benzodiazepines before hospitalization and those on them for long periods of time may demonstrate decreased sensitivity. Usually,

benzodiazepines are administered parenterally in the critical care setting, and the most commonly used agents are lorazepam and midazolam. Either lorazepam or midazolam may be given via intermittent or continuous IV infusion, but the two drugs have key differences relative to their pharmacokinetic, pharmacodynamic, and adverse effect profiles. Because it is more lipophilic, midazolam has a faster onset and shorter duration of action than lorazepam. However, because midazolam deposits in the adipose tissue, it can lead to variable and prolonged awakening when it is administered continuously over the course of several days.[82] Midazolam undergoes hepatic metabolism to an active metabolite, which is eliminated renally, whereas lorazepam is inactivated in the liver. Both agents should be used cautiously in renal and hepatic dysfunction because end-organ impairment prolongs the elimination half-life of both drugs. Lorazepam is formulated in a propylene glycol vehicle, which can accumulate at doses as low as 1 mg/kg/day and cause metabolic acidosis and AKI.[83,84] When benzodiazepines must be used, clinicians should carefully manage the dosing regimen to target the desired level of sedation at the lowest dose possible. Avoiding continuous infusions of benzodiazepines in favor of as-needed bolus doses based on symptoms of agitation may result in decreased total benzodiazepine exposure and a lower chance of benzodiazepine-related complications.

After thoroughly assessing J.A. and addressing reversible causes of agitation such as metabolic disorders and withdrawal syndromes, sedation with propofol should be considered if he remains agitated and his hemodynamics are adequate. Both propofol and dexmedetomidine are suggested the first-line sedatives according to current guidelines. However, because J.A. may require frequent awakenings for neurologic examinations, the faster offset of effect with propofol may make it more appropriate. J.A.’s blood pressure and HR should be monitored when propofol is started, and it should be titrated to a light level of sedation based on the RASS or the SAS. His triglyceride concentrations should be evaluated periodically if propofol is administered for several days, and clinicians should be

aware of the symptoms of PRIS in order to identify any potential episodes as soon as possible.

CASE 56-6

QUESTION 1: After receiving care in the ICU and remaining intubated and lightly sedated for several days, J.A.'s sedation is lightened, but he does not seem to be himself. He alternates between unresponsiveness and agitation. He is unable to tell caregivers where he is or answer simple questions.

Could J.A. be experiencing delirium?

Delirium is a symptom of acute brain dysfunction that involves the following combination of symptoms: acute change or fluctuation from baseline mental status, inattention, and disorganized thinking or altered level of consciousness.[85,86] Patients who are delirious may experience hallucinations, delusions, or hyperactivity, but these symptoms are not present in all delirious patients. In fact, three different forms of ICU delirium have been described based on the symptoms that patients demonstrate. In hyperactive delirium, patients are agitated, whereas in hypoactive delirium, they are calm or lethargic. Patients with mixed delirium fluctuate between these two subtypes.[43,44]

Delirium occurs at least once during the ICU stay in up to 80% of critically ill patients and is associated with negative patient outcomes, including increased mortality, ICU and hospital length of stay, long-term cognitive impairment, and health care costs.[87–90] Clinicians are more likely to fail to identify delirium if patients manifest hypoactive delirium rather than hyperactive delirium.[91] In order to identify patients who have delirium, current guidelines recommend that clinicians routinely assess patients several times each day using a validated delirium assessment tool.[43,44] The two recommended tools for assessing delirium are the Confusion Assessment Method for the ICU (CAM-ICU) and the Intensive Care Delirium Screening Checklist (ICDSC).

Based on his symptoms, J.A. is likely experiencing delirium. It is clear that his mental status has changed from baseline as "he does

not seem to be himself." In addition, the fluctuation between unresponsiveness and agitation combined with the inattention and disorganized thinking he is exhibiting by not being able to answer simple questions fulfill the other criteria of delirium. Clinicians should formally evaluate J.A. for delirium using a validated tool, such as the CAM-ICU or the ICDSC.

Case 56-6, Question 2: How should clinicians work to prevent and treat delirium in critically ill patients like J.A.?

There are a variety of modifiable and nonmodifiable risk factors associated with the development of delirium in critically ill patients.[43,44] Nonmodifiable risk factors include baseline dementia, hypertension, alcoholism, and greater severity of illness.[43,44,81,92] Current evidence suggests that benzodiazepine exposure, very deep sedation, and anticholinergic medications may increase the risk that patients develop delirium. Any association between opioids and propofol and delirium is unclear because of conflicting and limited evidence, respectively.

Evidence suggests delirium may be prevented with early mobilization protocols, in which nurses, physical therapists, and other clinicians assist critically ill patients in getting out of bed and ambulating. Studies of these protocols have demonstrated that they are safe and associated with significant reductions in delirium, hospital and ICU length of stay, and duration of mechanical ventilation when used in critically ill patients.[93,94] No pharmacologic therapy has been shown to prevent delirium in heterogeneous groups of critically ill patients.[43,44]

Although haloperidol and atypical antipsychotics have been used historically to treat delirium in critically ill patients, there is an absence of high-quality published literature in broad groups of critically ill patients supporting their effectiveness. Studies suggest these agents may not affect the duration of delirium in ICU patients.[95] Consequently, current guidelines recommend not using these agents for the treatment of delirium. Evidence suggests that using

dexmedetomidine instead of a benzodiazepine for the management of agitation may result in less delirium.[74,76,96]

Delirium can be prevented in patients like J.A. through the use of early mobilization protocols and minimizing risk factors for delirium, such as benzodiazepines. No pharmacologic strategy has been demonstrated to reduce delirium.

Stress Ulcer Prophylaxis in the Intensive Care Unit

The development of stress ulcers in critically ill patients is a common complication of ICU patients. Stress ulcers from critical illness began to be recognized in the 1960s when one study found that 5% of consecutive ICU patients had massive bleeding resulting from stress ulcers.[97] Stress ulcers usually develop in the mucosal layer of the stomach after high-stress events and can result in ulceration and progression to clinically significant bleeding.[98] Historically, up to 15% of patients in the ICU will develop an overt GI bleed if not given SUP, which makes it a preventable complication of critical illness.[99] However, more data indicate that this incidence is <5%.[100] Despite there being a large volume of research in this area, there lacks a consensus on the management and prevention of stress ulcers.

Patients with serious illness or trauma can develop stress ulceration within hours of the inciting event. There are various degrees of stress ulceration, and they can develop from hours to weeks after hospital admission. Critical illness often leads to increased vasoconstriction, decreased cardiac output, and a pro-inflammatory state, which leads to splanchnic hypoperfusion.[101] The cause of stress ulceration in the ICU evolves from several factors, including gastric acid secretion, mucosal ischemia, and upper intestinal reflux. This leads to the lack of perfusion and oxygen delivery to intestinal cells, resulting in mucosal damage.

CASE 56-7

Question 1: A.K. is a 76-year-old male admitted to the medical ICU for likely sepsis from a urinary source. He was acidotic on arrival to the ED and intubated. He has a PMH of hypertension, diabetes, pulmonary embolism, several urinary tract infections, and reports drinking 10 to 12 beers/day. His home medications include atorvastatin 20 mg by mouth daily, lisinopril 20 mg by mouth daily, metoprolol XL 100 mg by mouth daily, metformin 1000 mg by mouth twice daily, and warfarin 7.5 mg by mouth daily. Labs on arrival are Na 131 mEq/L, K 3.2 mEq/L, blood urea nitrogen (BUN) 33 mg/dL, SCr 2.7 mg/dL, Hct 20%, platelet count (Plt) 47 × 10^3/μL, and INR 5.9.

What risk factors does A.K. have that would qualify him for SUP?

Several risk factors have been identified to help determine who should get SUP. One study[102] investigated 2252 ICU patients and found that there were two major risk factors for clinically important GI bleeding: (a) mechanical ventilation for >48 hours (OR 15.6) and (b) coagulopathy (OR 4.3) defined as a Plt of <50,000 mm^3, an INR of >1.5, or a partial thromboplastin time of more than two times the control value.[96] Other risk factors that have been identified include head injury, burn involving >35% of body surface area, partial hepatectomy, hepatic or renal transplantation, multiple trauma with Injury Severity Score of >16, spinal cord injury, hepatic failure, history of gastric ulceration or bleeding during year before admission, and two or more of the following: sepsis, length of ICU stay >1 week, occult bleeding for at least 6 days, and administration of high-dose corticosteroids (>250 mg/day of hydrocortisone or equivalent).[97] Most clinicians will start SUP in patients who have one or more major risk factor. However, the utility of SUP in the ICU is controversial, given inconsistent demonstration of benefit. One clinical trial comparing pantoprazole to placebo found no difference in 90-day mortality (RR 1.02, 95% CI 0.91–1.13), although pantoprazole was associated with a decreased risk of clinically important GI bleeding (RR 0.58, 95% CI 0.40–0.86).[100] The guidelines for SUP are expected to be updated in the next few years, given the recent advances in this field.[103] For patients who have multiple minor risk factors or patient groups excluded from major trials (eg, spinal cord injury, traumatic brain injury, or thermal injury), SUP is determined by the primary team on a case-by-case basis.

A.K. has a major risk factor in that he is likely to be intubated for at least 48 hours. For this reason, he should be started on SUP.

Case 56-7, Question 2: What medication could be initiated in A.K. to reduce his chance of developing a stress ulcer?

The mechanisms to pharmacologically prevent against stress ulcers are to layer the gastric lining with a protective coating, lowering the gastric pH by neutralizing gastric acid secretions, or by preventing gastric acid secretion. The three classes of medications used for SUP are histamine 2-receptor antagonists (H_2 blockers), PPIs, and protective barrier-producing medications. A fourth class of medication, prostaglandin analogs, has been used for SUP in the past, but it has not been shown to be beneficial and is not discussed in this chapter.[104]

After deciding to start SUP, the next decision to make is what agent to use. The two most commonly used classes of medications are H_2 blockers and PPIs. H_2 blockers were found to be superior to antacids and sucralfate in two different trials.[105,106] There has been an increasing amount of research comparing PPIs to H_2 blockers, but there still lacks a consensus on what agent to use based on conflicting data. One randomized trial comparing H_2 blockers to PPIs in ICU patients requiring mechanical ventilation found no difference in in-hospital mortality (RR 1.05, 95% CI 1.0–1.1; *P* = .054). However, there was a decrease in clinically important upper GI bleeding with PPI use (RR 0.73, 95% CI 0.57–0.92). One of the primary study limitations was that 20% of patients randomized to H_2 blockers received a PPI at some point during their ICU stay.[107] A cohort study of over 35,000 ICU patients showed H_2 blockers had a lower risk of GI hemorrhage compared to PPIs (6% vs 2%; adjusted OR, 2.24; 95% CI, 1.81–2.76).[108] This differed with a previous meta-analysis of 13 randomized trials showing reduced GI bleeding in the PPI prophylaxis group compared to the H_2 blocker group (1.3% vs 6.6%; OR, 0.30; 95% CI, 0.17–0.54).[109] The most recent meta-

analysis on this topic, evaluating 74 trials and over 39,000 patients, found that there was no difference between PPIs and H_2 blockers on mortality (RR 1.05, 95% CI 0.97–1.14), although PPIs may be associated with a lower rate of clinically important GI bleeding (RR 0.69, 95% CI 0.45–0.93).[110] Common agents used for SUP are provided in **Table 56-4**.

Table 56-4

Common Agents Used for Stress Ulcer Prophylaxis

Agent	Trade Name	Adult Dosing	Routes	Generic Available
Proton-Pump Inhibitors				
Dexlansoprazole[a,b]	Dexilant®	30 or 60 mg once daily	Oral	Yes
Esomeprazole[a,b]	Nexium®	20–40 mg once daily ≥1 hour before a meal	Oral, IV	Yes
Lansoprazole[a,b]	Prevacid®	15 or 30 mg once daily before a meal	Oral	Yes
Omeprazole[a,b]	Prilosec®	20 or 40 mg once daily on an empty stomach ≥1 hour before a meal	Oral, IV	Yes
Pantoprazole[a,b]	Protonix®	40 mg once daily (administer suspension 30 minutes before a meal)	Oral, IV	Yes
Rabeprazole[a,b]	Aciphex®	20–60 mg once daily (administer capsule 30 minutes before a meal; if capsule is opened and dispersed on food, administer within 15 minutes of preparation)	Oral	Yes
Histamine H_2 Antagonists				
Famotidine[a,b]	Pepcid®	20 mg twice daily (20 mg daily for CrCl <30 mL/minute)	Oral, IV	Yes
Ranitidine[a–c]	Zantac®	150 mg twice daily (150 mg once daily if CrCl <50 mL/minute)	Oral, IV	Yes
Gastric-Coating Agents				
Sucralfate[a,b]	Carafate®	1 g four times daily	Oral	Yes

CrCl, creatinine clearance; FDA, Food and Drug Administration; IV, intravenous.

[a]Off-label indication for stress ulcer prophylaxis.

[b]Able to administer oral formulation via feeding tube, dependent on formulations available.

[c]Currently not available via oral route owing to recall by FDA owing to contaminant.

An area of debate is whether a patient who is receiving full caloric supplementation through tube feeds requires pharmacologic SUP. Enteral nutrition has been shown to increase gastric pH to >3.5 more often than H_2 blockers or PPIs.[111] Animal models have shown a protective benefit of alimentation on the gastric mucosa from stress-related damage. The practice of whether to discontinue

pharmacologic SUP if enteral nutrition has been started varies among different institutions.

CASE 56-7, QUESTION 3: Are there any adverse effects associated with placing A.K. on SUP?

Although pharmacologic SUP has shown to decrease bleeding events, it appears this does not come without risk. Gastric acid plays an important part in sterilizing the upper GI tract, and alterations of physiologic pH have shown adverse effects. The higher pH level allows increased colonization of potentially pathogenic bacteria in the GI tract.

After the implementation of SUP as a standard of care in ICUs, several studies and meta-analyses identified an increased risk of nosocomial pneumonia and *C. difficile* infections in patients receiving H_2 blockers or PPIs. The increased pH levels as a result of these medications have been proposed as a mechanism of action. Available data are conflicting on the incidence of nosocomial pneumonia among the agents that alter gastric pH. Two studies showed an increased risk for H_2 blockers compared to those who did not receive acid-suppressive therapy or sucralfate.[106,112] One meta-analysis showed no difference on the incidence of nosocomial pneumonia when comparing PPIs to H_2 blockers.[109] Data have also shown that PPIs had a higher incidence of pneumonia compared to H_2 blockers.[108] Both PPIs and H_2 blockers have been associated with an increased risk of *C. difficile* infection.[113] Most of these studies are observational and did not control for comorbidities, so there is still much debate in the critical care community.

Although sucralfate does not alter gastric pH, it can interfere with the absorption of many medications, including ciprofloxacin, phenytoin, digoxin, and levothyroxine. To help prevent this, sucralfate should be given 2 hours after these medications. Sucralfate has been shown to bind to tube feeds and cause bezoars (solid mass within GI tract) and cannot be given through duodenal or jejunostomy feeding tubes. In addition, sucralfate is an aluminum

salt, which increases the risk of aluminum toxicity (eg, altered mental status, seizure) with prolonged use in patients with renal dysfunction. There are several options of SUP for A.K. A PPI or H_2 blocker would be the best choice. Because he is intubated and does not have a feeding tube yet, an IV H_2 blocker such as famotidine (renally dosed) or IV PPI such as pantoprazole would be appropriate.

Glycemic Control in Intensive Care Unit Patients

Critically ill patients may develop hyperglycemia for a variety of reasons, including acute illness, preexisting disease states, and the effects of medications. Glycemic goals and treatments differ for patients managed in the ICU as compared to those treated in other settings, including patients receiving chronic therapy for diabetes as outpatients.

CASE 56-8

QUESTION 1: D.M. is a 74-year-old female admitted to the medical ICU for pneumonia and a chronic obstructive pulmonary disease (COPD) exacerbation. Her PMH includes hypertension, hyperlipidemia, and COPD. On the first day of her ICU stay, she decompensates and develops respiratory failure requiring intubation. Among other laboratory abnormalities, her blood glucose concentration is 212 mg/dL.

How should clinicians manage D.M.'s hyperglycemia?

A variety of biochemical mediators, such as cortisol, glucagon, catecholamines, and growth factor, may rise in critical illness and contribute to hyperglycemia by increasing glycogenolysis and decreasing gluconeogenesis.[114] In addition to the effects of critical illness, inadequately treated diabetes, adverse effects of drugs like corticosteroids, and exposure to caloric loads from nutritional regimens or dextrose used as a base for IV solutions can contribute to hyperglycemia. Although studies suggest that hyperglycemia of critical illness is associated with poor outcomes, it is not clear whether hyperglycemia leads to worsened outcomes or if it is simply

an indicator of disease severity.[115–117] In addition to the magnitude of hyperglycemia, glycemic variability has also been associated with negative outcomes.[118]

The optimal blood glucose range for critically ill patients has not been definitely established.[119] Uncontrolled hyperglycemia has the potential to cause severe effects. Single-center studies of surgical and medical ICU patients treated with intensive insulin therapy to achieve blood glucose concentrations between 80 and 110 mg/dL initially suggested improved outcomes, but these findings were not replicated in subsequent trials.[120,121] In fact, some studies suggest aggressive insulin therapy may increase mortality as compared to liberal blood glucose control typically targeting 140 to 180 mg/dL.[122–126] It has been suggested that the higher rates of hypoglycemia observed in patients receiving intensive insulin may increase mortality by leading to neurologic complications. On the basis of these findings, the American Diabetes Association recommends that insulin is administered to ICU patients when blood glucose concentrations exceed 180 mg/dL, and it is used to maintain blood glucose concentrations between 140 and 180 mg/dL. In some critically ill patients, such as postsurgical patients and those who have had cardiac surgery, targeting blood glucose ranging between 110 and 140 mg/dL may be appropriate if this practice does not result in significant hypoglycemia. Because parenteral administration of insulin achieves more rapid and reliable results than oral therapy, patients are typically managed with subcutaneous insulin or IV insulin infusions while in the ICU. Subcutaneous regimens typically include as-needed sliding scale insulin involving rapid- or short-acting formulations. Scheduled long-acting insulin may be combined with sliding scales in some patients; however, clinicians should cautiously dose insulin in order to avoid hypoglycemia. Some patients with significant insulin needs may benefit from a continuous IV infusion of regular insulin that is carefully titrated to the blood glucose goal.

Because D.M.’s blood glucose exceeds 180 mg/dL, clinicians should attempt to achieve better glycemic control. First, dextrose-containing fluids should be minimized, and any enteral nutrition she

is receiving should be evaluated. Medications, like steroids, that might increase her blood glucose concentrations should be assessed and minimized as possible. If her blood glucose remains high after these measures, it would be appropriate to initially consider sliding scale insulin with regular insulin.

INTERPROFESSIONAL CARE

Interprofessional care is a unique and critical aspect to patient care in the ICU, supported by the Society of Critical Care Medicine guidelines in 2003.[127] The role of the pharmacist in the ICU care team was most recently supported by a position paper in 2020.[128] Throughout the practice experiences that pharmacy trainees have, they may encounter multiple professions they may not have collaborated with before that experience. It is through this teamwork that the patient has optimal outcomes, given the shared expertise of each clinician. Examples of clinician roles, responsibilities, and potential learning points are detailed in **Table 56-5**.

Table 56-5
Examples of Clinician Roles, Responsibilities, and Learning Points in the ICU

Clinician	Roles and Responsibilities	Learning Points
Nurse	▪ Medication administration ▪ Patient monitoring	▪ Types of lines and tubes ▪ Technology (eg, intravenous infusion pumps)
Nutritionist	▪ Development of enteral and parenteral nutrition plans	▪ Patient nutrition goals ▪ Development of total parenteral nutrition
Pharmacist	▪ Drug information ▪ Order verification ▪ Medication safety	▪ Interpretation of published literature ▪ Development of medication guidelines

Clinician	Roles and Responsibilities	Learning Points
Physical therapist	▪ Development of mobility ▪ Rehabilitation	▪ Effect of medications on mobility
Provider[a]	▪ Diagnosis ▪ Orders (eg, imaging, labs, medications)	▪ Diagnostic procedure interpretation (eg, cardiac rhythm, imaging)
Respiratory therapist	▪ Administration of inhaled medications ▪ Management of respiratory devices (eg, mechanical ventilation)	▪ Inhaled medication logistics ▪ Mechanical ventilation settings

[a]Includes nurse practitioners, physicians, and physician assistants.

Multiple Sclerosis

Melody Ryan

CORE PRINCIPLES		CHAPTER CASES
1	Multiple sclerosis (MS) is a chronic inflammatory and degenerative disease of the central nervous system in which demyelination and axonal damage occur. MS can take one of several forms: relapsing-remitting, secondary-progressive, or primary-progressive are the most common forms.	**Case 57-1 (Questions 1, 5)**
2	The diagnosis of MS is based on clinical symptoms and is supported by magnetic resonance imaging (MRI) and laboratory testing (cerebrospinal fluid oligoclonal bands and immunoglobulin-G synthesis rate; evoked potential testing). In an individual patient, dissemination in space and time must be demonstrated before the diagnosis of MS is made.	**Case 57-1 (Questions 1, 5)**

3	Glucocorticoids are the agents of choice for treatment of acute MS relapses.	**Case 57-1 (Question 7)**
4	Clinically isolated syndrome (CIS) is a term used to describe a first demyelinating neurologic event before the diagnosis of MS has been made. When a patient presents with CIS and MRI abnormalities, progression to clinically definite MS is likely, and therapy with glatiramer acetate, interferon-β, or teriflunomide helps to prevent this progression.	**Case 57-1 (Questions 1, 2)**
5	The choice of drug for relapsing forms of MS is highly individualized with consideration of disease activity and medication adverse effects. The choice of treatment is often based on provider or patient preference.	**Case 57-1 (Questions 3, 5–9)** **Case 57-2 (Question 1)**
6	Adherence to MS therapy is low and a potential point for intervention.	**Case 57-1 (Question 4)**
7	Patient monitoring is necessary and specific for each MS therapy.	**Case 57-2 (Question 2)**

fatigue, cognitive dysfunction, spasticity, bowel dysfunction, dysphagia or dysarthria, and pseudobulbar affect. These symptoms may require both nonpharmacologic and pharmacologic therapies.

INTRODUCTION

Multiple sclerosis (MS) is a chronic inflammatory and degenerative disease of the central nervous system (CNS) in which demyelination and axonal damage occur.[1] The disease has a mean age at onset of 30 years, with diagnoses typically occurring between ages 20 and 50 years.[1] Because of the young age at onset, MS has a dramatic effect on employment and, in fact, is the most common cause of disability in young adults.[2] Overall life expectancy is decreased by about 7 years compared with age- and sex-matched control subjects.[3] Cardiovascular, cerebrovascular, cancer, and infectious causes of death are the most commonly reported, similar to a control population, but occurring in higher frequencies in patients with MS.[3,4] Health-related quality of life is lower in patients with MS than in the general population, and this decrease is related to the severity of MS.[5]

MS affects ~0.1% of the U.S. population (900,000 people) and about 2.2 million people worldwide.[2,4] Females are two to three times more likely to have MS than males.[1] Many environmental and genetic factors have been associated with MS (**Table 57-1**); however, the causal nature of any of these factors has yet to be established.[1,2,6–11] Current thought is that an environmental trigger acting in a genetically susceptible individual is the probable cause of MS.[6]

Table 57-1
Factors Associated With Multiple Sclerosis

Female Sex[2]	Low Sun Exposure[1,6]
Higher latitudes of residence[6,7]	Low serum concentrations of vitamin D (25-hydroxyvitamin D)[2,6,8]
Northern European heritage[6]	High serum antibody titers to the Epstein–Barr virus nuclear antigens[6,9]
Infectious mononucleosis[2,9]	Tobacco smoking[2,10]
Childhood and adolescent obesity[11]	

MS is most frequently encountered between 40 and 60 degrees North or South latitude. Regions with a high prevalence include Western and Northern Europe, Canada, Russia, Israel, Northern United States, New Zealand, and Southeast Australia.[4,7] Additionally, relapse rates may also vary seasonally with latitude.[12] This finding has spurred many research studies and hypotheses. One hypothesis is that the development of MS is related to sunlight exposure or vitamin D.[8] Higher serum concentrations of 25-hydroxyvitamin D (the major circulating form and the one that is measured by clinical laboratory testing) are associated with reduced hazard of an MS relapse, and lower concentrations are associated with higher rates of MS diagnoses.[8] Genetically, lack of the vitamin D receptor and cytochrome P-450 (CYP) 27B1 (encodes the enzyme responsible for vitamin D activation converting 25-hydroxyvitamin D to 1,25-hydroxyl-vitamin D) is associated with impaired immune system.[11] Some investigators have found links between season of birth and development of MS, suggesting that maternal vitamin D status may be important.[13] Relapses also follow a seasonal pattern, with peaks in the early spring and troughs in the autumn in both hemispheres, further suggesting a role of vitamin D in relapses.[12]

Epstein–Barr virus (EBV) is a ubiquitous infection; however, high EBV titers and a history of infectious mononucleosis both increase risk of developing MS.[9,11] Further, there is some evidence linking the

human leukocyte antigen (HLA)-DRB1*1501 genotype to an increased risk of developing MS in patients with either EBV or infectious mononucleosis.[9] Smoking is a risk factor, with higher levels of smoking conferring greater risk.[2,10,11] There is also evidence that obesity in childhood or adolescence increases the risk of developing MS.[11]

A genetic predisposition to the development of MS is likely. First-degree relatives of people with MS have a risk of MS that is 10 to 25 times greater than the general population; the concordance rate in identical twins is 35%.[6] There are probably several genetic factors that increase the risk for MS, including HLA type and various single-nucleotide polymorphisms that control T-cell receptors, B cells, vitamin D receptors, and estrogen receptors.[8,14] A specific major histocompatibility complex (MHC) associated with MS is HLA-DRB1*1501 class II,[9] but 233 different genetic variations have been associated with MS.[15] No genetic association has been found for a particular clinical course or rate of progression.[15]

Although MS is more prevalent in Caucasian populations in the United States, there is evidence that African American patients may be more likely to have primary-progressive forms and may have a more severe disease course. The reasons for these differences are poorly understood but may have genetic, environmental, and socioeconomic bases and prevalence among African Americans may be increasing.[16–18]

MS is generally characterized as one of three main types according to the presentation and clinical course of the disease: relapsing-remitting MS, secondary-progressive MS, and primary-progressive MS. These three types of MS are distinguished by their natural histories. Relapsing-remitting MS was named for the relapses (also called exacerbations or attacks) of clinical disease activity that alternate with periods of symptom remission. Recovery during the remission periods can be complete, or the patient may continue to have some clinical deficits.[19] Between 80% and 90% of patients have relapsing-remitting MS when they are first diagnosed.[20,21] Patient registry data provide insight regarding the prognosis of those with relapsing-remitting MS. Patients diagnosed

with relapsing-remitting MS at onset have slower progression to disability than patients with primary-progressive MS; patients having complete or near-complete recovery from the first attack of MS have a longer time to disability compared with those with significant persistent deficits after the first attack.[21]

Approximately 80% of patients initially diagnosed with relapsing-remitting MS experience a secondary-progressive form in which fewer relapses occur, but disability continues to progress.[2] The cause of the conversion from relapsing-remitting MS to secondary-progressive MS is unknown, but it has been hypothesized that the change occurs when axonal loss in the CNS reaches a critical threshold.[21] The time to development of secondary-progressive MS is quite variable. The usual time to conversion is 20 to 25 years after diagnosis, with median patient age at the time of conversion of 43 years; however, it may occur much sooner.[19,21] It is not known how treatment affects this process. In one study, the number of early relapses (within 2 years of diagnosis) was associated with a shorter time to development of secondary-progressive MS.[21] Therefore, early treatment with a therapy that reduces relapses might be expected to delay the development of secondary-progressive MS.

Approximately 10% to 15% of patients have primary-progressive MS.[21] This type of MS is progressive from onset with occasional minor improvements or periods of stabilization.[19] Primary-progressive MS is more common in patients who are older than age 50 years at diagnosis.[2] Select studies have found this form to be more common in males, but others have found no association with sex.[21] Non-Hispanic Blacks have primary-progressive MS compared to other racial and ethnic groups.[17]

In the absence of treatment, patients who initially present with relapsing-remitting MS develop average Expanded Disability Status Scale (EDSS) scores of 4.0 or higher (indicating significant disability) by 7 years after diagnosis.[4] The EDSS is a scale commonly used in MS to measure the level of disability and progression of the disease.[22] Some predictors of a more progressive disease course include male gender, multisystem symptoms, incomplete recovery from the initial episode, progressive disease from the time of

diagnosis, older age at onset, and abnormal baseline magnetic resonance imaging (MRI) results.[19,21] Although patients present with different types of MS, once progression begins, all forms of progressive MS follow a similar time course for subsequent progression.[19]

A classification system is used to denote disease activity and progression over a 1-year period.[23] Patients with new, active MRI lesions or with clinical relapses within a specified time frame are classified as active, whereas those without new lesions or relapses are classified as inactive. In a similar way, patients are categorized as progressing if they have steadily increasing objectively documented neurologic dysfunction without recovery or nonprogressing. For example, a patient with relapsing-remitting MS who has had a clinical relapse in the last year, but who had full recovery, would be classified as relapsing-remitting MS-active and not progressing.[23] Because MS begins during young-to-middle adulthood, there is a large economic burden associated with the disease. MS has the fourth most expensive drug costs among commercially insured patients.[24] One study in which newly diagnosed patients were matched to healthy control subjects found that patients with MS were 3.5 times as likely to be hospitalized, twice as likely to have at least one emergency department visit, and 2.4 times as likely to have at least one visit for physical, occupational, or speech therapy during the course of a year.[25] These services are associated with a mean annual total health care cost of $62,500, and disease-modifying therapy makes up almost 70% of the total health care costs.[26] These estimates do not consider the loss of employment or loss of caregiver employment. One study found that earnings of people with MS were less than their matched counterparts, beginning 1 year before diagnosis and increasing during the diagnosis year (15% less than controls) and at 5 years after diagnosis (27% less than controls).[26]

Ten years after diagnosis, 50% to 80% of patients with MS are unemployed. Surprisingly, only 15% of unemployment is related to physical restrictions.[27] Of the factors most often cited as leading to unemployment, only decreased walking ability relates to physical

disability. The other common factors are increased age, decreased verbal fluency, and loss of memory.[27]

PATHOPHYSIOLOGY

Many aspects of the pathophysiology of MS remain unclear, although research in this area is progressing rapidly. Foremost in unresolved issues is the identity of the actual initiating factor for the autoimmune and inflammatory processes that characterize MS. Through the years, several dozen triggers have been proposed. Current thinking is that a genetically susceptible individual has an environmental factor that triggers the immune system to cause MS.[6]

There are two pathologic processes that occur during MS. The first is inflammatory. During this process, the body mounts an autoimmune attack on the myelin covering of nerve fibers of the white matter in the CNS. These areas of demyelination are visualized as plaques or lesions and are seen on brain tissue directly (eg, on autopsy) or on MRI with contrast agents (**Fig. 57-1**).[14] It is this inflammation that causes the relapses that are seen clinically, and it is the resolution of these relapses that is seen as remission.

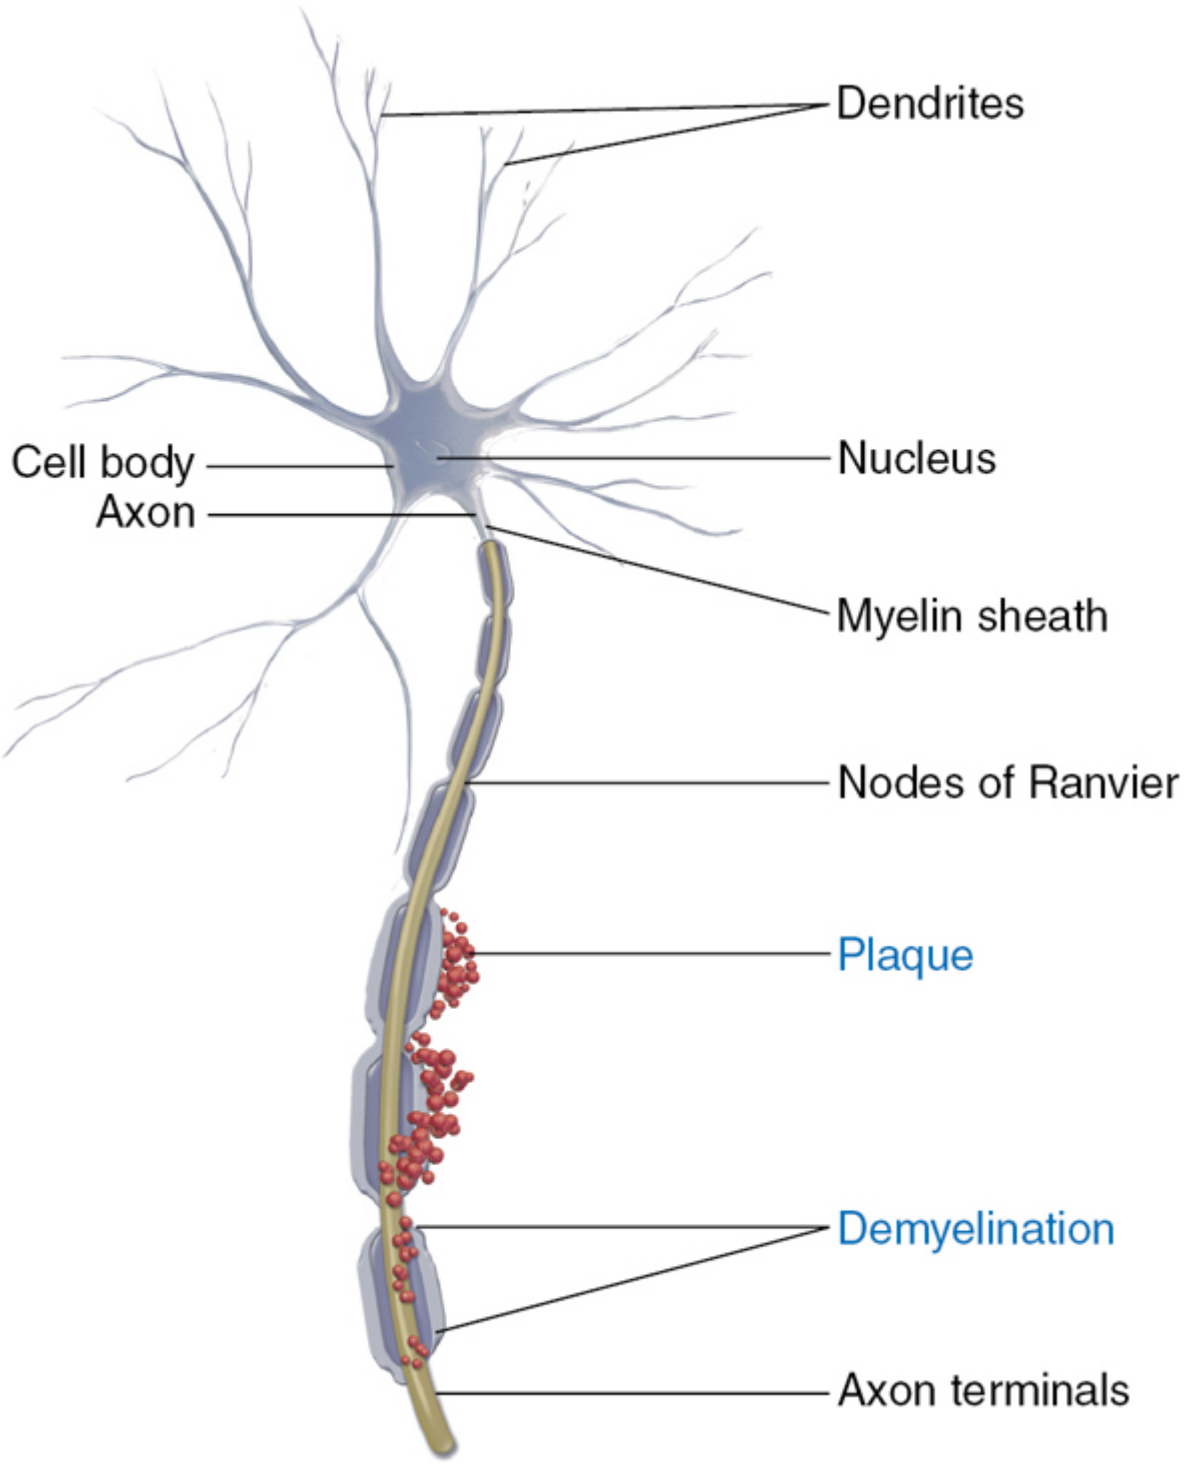

Figure 57-1 Myelin destruction in multiple sclerosis.

The second process is neurodegenerative, during which the axons of nerves in brain white matter are damaged, some irrevocably. This neurodegeneration causes a progressive disability when

transmission through the nerve cell is slowed or fails completely. It is cumulative with time and may be irreversible. It is not known whether the inflammatory or neurodegenerative process occurs first in MS or whether they are simultaneous.[14] Additionally, the pathophysiology of progressive MS likely differs substantially from relapsing forms of MS with greater axonal loss, but specific, treatable issues are elusive.[28]

Inflammation

The inflammatory cascade in MS is complex. Various types of T cells play a role early in the process.[14] The unknown antigen couples with MHC molecules.[2,6] These antigen–MHC pairs encounter antigen-presenting cells (APCs) such as dendrites, macrophages, and microglia.[9,22] T cells recognize this antigen–MHC–APC complex, become activated, and initiate the immunologic cascade.[14] Under normal circumstances, regulatory T cells (T_{reg}) monitor for and control autoimmune T-cell formation in the periphery. It has been hypothesized that T_{reg} cells malfunction in people with MS.[14] The activated T cells then retreat to the lymphatic tissues in the body, such as the spleen and lymph nodes, to expand.[14] At the appropriate time, the T cells exit the lymphatic tissues and rejoin the circulation. Sphingosine-1-phosphate (S1P), a small, circulating lipid molecule, is important in this process. For the T cells to exit the lymphatic tissues, the S1P receptor 1 must be expressed on their surface.[29] The T cells follow an S1P concentration gradient to exit the lymphatic tissues and join the circulation. The activated T cells must cross the blood–brain barrier to attack myelin in the CNS. An adhesion molecule, $\alpha_4\beta_1$-integrin (VLA4), is found on the surface of T cells.[14] When the T cells approach the blood–brain barrier, they slow and bind to the α_4-integrin and p-selectin glycoprotein ligand 1. This bonding allows the T cells to transmigrate through the endothelial cells of the blood vessel.[30]

In the perivascular space, the T cells must be reactivated by new APC.[30] Through the action of matrix metalloproteinases 2 and 9, the activated T cells invade the parenchyma of the brain.[30] Once

ensconced in the brain, the T cells begin to secrete various pro-inflammatory cytokines that further stimulate the inflammatory cascade, including stimulation of microglia.[30] The microglia produce proteolytic enzymes, lipolytic enzymes, reactive oxygen species, reactive nitrogen species, excitotoxins, and more pro-inflammatory cytokines. Activated microglia can also serve as APCs for activation of additional T cells.[30] Nitric oxide, a reactive nitrogen species, is increased during inflammation and can inhibit mitochondrial respiration, inhibit the sodium–potassium adenosine triphosphatase pump, and cause the intracellular release of calcium. The excess calcium leads to degenerative processes within the cell.[21]

Although the role of T cells is central to MS pathology, the role of B and natural killer (NK) cells is much less clear. B cells may be involved in antigen presentation, production of cytokines, and the production of the immunoglobulin found in the cerebrospinal fluid (CSF) of patients with MS.[31,32] Antibodies produced by B cells in the CSF may target myelin oligodendrocyte glycoprotein or myelin basic protein.[31] Among the subtypes of B cells, memory B cells may be the most pathogenic in MS.[32] NK cells have been postulated to have both helpful and deleterious effects.[30]

At some point, the resolution of inflammation begins. During the inflammatory cascade, myelin is broken down, and this myelin debris inhibits remyelination. The microglia use phagocytosis to clear myelin structures, axons, apoptotic cells, and myelin debris from the area of inflammation.[30] After this process, the microglia begin to produce immunomodulatory cytokines.[30] Helper T type 2 cells become more prominent and begin secreting immunomodulatory cytokines as well.[30]

Remyelination then begins; however, some evidence suggests that the ability of the body to remyelinate decreases with age.[30] Microglia produce more cytokines and some growth factors that cause oligodendrocyte progenitor cells to migrate to the area. Remyelination occurs when oligodendrocyte progenitor cells differentiate into new oligodendrocytes.[30] Sphingosine-1-phosphate receptors 1 and 5 present on oligodendrocytes appear to help with differentiation.[33] Remyelination may not be complete and, in some

cases, does not occur at all. The myelin also may be thinner and shorter than the original myelin.[30]

Neurodegeneration

Axonal injury can occur throughout the course of the disease and may even occur before any clinical symptoms.[34] Inside chronic MS lesions, there are 60% to 70% fewer axons compared with other white matter in the same patient.[34] In addition to producing myelin, oligodendrocytes support axons through the production of insulin-like growth factor type I and neuregulin; thus, axons can die without the support of the oligodendrocytes. However, axonal loss has been demonstrated at sites separate from MS lesions, particularly the thalamus.[34] Although oligodendrocytes provide trophic support for the axons, they also inhibit new growth to prevent random neurite sprouting. Three myelin-associated inhibitor factors, myelin-associated glycoprotein, Nogo-A, and oligodendrocyte myelin glycoprotein, lie in the sheath of myelin closest to the axon, where they prevent this sprouting.[34]

Microtubules are also important for neurite growth. The assembly of microtubules is controlled by collapsin-response mediator protein 2 (CRMP-2).[34] When CRMP-2 is phosphorylated, neurite growth is inhibited.[34] *Ras* homolog gene family, member A (RhoA)–guanosine triphosphate (GTP), has action on both the myelin-associated inhibitory factors and CRMP-2. The myelin-associated inhibitory factors signal RhoA–GTP to neurite retraction rather than growth.[34] It also activates Rho kinase, which phosphorylates CRMP-2.[34] Myelin normally allows saltatory, fast conduction (ie, conduction via leaps) at the nodes of Ranvier; thus, loss of myelin slows or prevents transmission of nerve impulses.[34]

In the demyelinated state, sodium channels under the myelin sheath may become functional to allow improved nerve conduction.[34] The activation of sodium channels results in sodium entry into the cell. The excess sodium activates the sodium–calcium exchanger to export sodium and import calcium, fueling the degenerative

processes within the neuron.[34] Additionally, increased numbers of glutamate-regulated α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors are seen in demyelinated axons. Activation of these receptors results in increased levels of intracellular sodium and calcium, further contributing to neurodegeneration.[34]

CLINICAL PRESENTATION

Because the demyelination associated with MS can occur in any part of the CNS, many different symptoms are associated with the disease. At first presentation, the most common clinical symptoms are sensory disturbances, particularly of the extremities, partial or complete visual loss, motor dysfunction of the limbs, diplopia, and gait dysfunction.[2] Two demyelinating syndromes are so distinct that they have been recognized, named, and deserve particular mention: optic neuritis and transverse myelitis. Optic neuritis is the acute demyelination of the optic nerve. Symptoms may include ocular pain, blurred vision, or changes in color perception.[35] Transverse myelitis is impairment of motor control or sensory function, or control over bladder, bowel, and sexual functions that are consistent with a lesion at a specific point in the spinal cord, but without a structural cause such as a herniated disc.[36]

As concern has developed about neurodegenerative changes that occur early in the course of MS, there has been more interest in very early treatment after the emergence of symptoms to delay or decrease the development of MS. The term clinically isolated syndrome (CIS) describes a first demyelinating neurologic event involving the optic nerve, cerebrum, cerebellum, brainstem, or spinal cord.[37] Up to 85% of people with MS may first present with CIS.[37] Of those who present with CIS, 63% will develop MS during the ensuing 20 years.[38]

Patients younger than 40 years are more likely to convert from CIS to clinically definite MS than those age 40 years or older.[39] Patients

with optic neuritis as the presenting diagnosis are less likely than those with other symptoms to develop clinically definite MS. The presence of oligoclonal bands in the CSF, low serum concentrations of vitamin D, and multiple lesions on MRI are associated with a particularly high risk of development of MS.[38,39]

Occasionally, MS-type lesions will be visible on an MRI scan performed for other reasons. If the patient has no other symptoms, this condition is known as radiologic-isolated syndrome.[40] About 30% to 50% of these patients have a clinical episode within 5 years of the detection of their MRI abnormality.[40] Younger patients, males, and those with lesions on the spinal cord were more likely to develop a CIS.[40] No treatment is suggested for patients with these findings at this time.[40]

With time and with neurodegeneration, many other symptoms can develop in people with MS. The most common symptoms are listed in **Table 57-2**.[41–48]

Table 57-2
Common Symptoms in Chronic Multiple Sclerosis

Symptom	Prevalence (%)
Sexual dysfunction[41]	40–90
Walking problems or impaired ambulation[42]	45–90
Pain[43]	30–90
Bladder dysfunction[43]	50–90
Fatigue[44]	30–80
Cognitive dysfunction[43]	40–65
Spasticity[45]	60
Bowel dysfunction[43]	50
Depression[46]	50
Dysphagia or dysarthria[47]	40
Pseudobulbar affect[48]	10

DIAGNOSIS

When patients first present for medical care with symptoms of MS, diseases as diverse as infections, cancers, vascular disease, or other inflammatory demyelinating diseases are commonly part of the differential diagnosis. Thus, the addition of MRI and other laboratory findings can help with the diagnosis. At other times, the diagnosis is not apparent until the occurrence of a second attack.[49]

Diagnostic criteria have been proposed in an effort to standardize diagnoses of MS and to promote earlier treatment. The initial criteria stated that the patient must have experienced at least two demyelination-related episodes separated by time and space (ie, at least two episodes involving distinct regions of the CNS).[1] Guidelines proposed in 2001 and revised in 2005, 2010, and 2017 allow for the use of MRI and CSF findings to fulfill these time and space criteria after an initial clinical attack.[1] In particular, the 2017 criteria also allow for the presence of oligoclonal bands in the CSF to substitute for the dissemination in time criteria.[1] Primary-progressive MS is diagnosed when there is a continuous progression of neurologic symptoms during a 1-year period with characteristic MRI and CSF findings.[1]

OVERVIEW OF TREATMENT

Although the mechanisms of action of MS pharmacotherapies are diverse, they all can be generally categorized as immunomodulating agents. To date, all therapies for MS have targeted the inflammatory response rather than the accompanying neurodegeneration features of the disease.

Treatment of Acute Relapses

Corticosteroids are used in the treatment of MS to control inflammation during acute relapses. Although most patients respond to treatment with corticosteroids, some do not. These agents have several actions that contribute to their acute anti-inflammatory effects. Corticosteroids increase the activity of T_{reg} cells, reduce the activity of T and B cells, reduce adhesion molecule production, and reduce pro-inflammatory cytokines.[50]

Treatment of Relapsing-Remitting Multiple Sclerosis

Most of the therapeutic research conducted in MS has focused on the relapsing-remitting form of the disease. This is the most common form of MS at presentation, and it has an important inflammatory aspect. The agents that are currently U.S. Food and Drug Administration (FDA)-approved for MS include alemtuzumab, anti-CD20 antibodies (eg, ocrelizumab, ofatumumab) β-interferons, cladribine, fumarates (eg, dimethyl fumarate, diroximel fumarate, monomethyl fumarate), glatiramer acetate, mitoxantrone, natalizumab, S1P-receptor modulators (eg, fingolimod, ozanimod, ponesimod, siponimod), and teriflunomide.

ALEMTUZUMAB

Alemtuzumab is a monoclonal antibody aimed at CD52. It reduces the population of circulating B and T cells. The peripheral circulating lymphocytes are undetectable within minutes of infusion.[51] These cells repopulate, but fairly slowly; B cells have a median recovery time of 8 months, $CD8^+$ T cells 20 months, and $CD4^+$ T cells 35 months. However, some patients took as long as 12 years to reach baseline levels.[51] Because of the significant lymphocyte depletion, alemtuzumab is thought to “reset” the immune system, a process called immune reconstitution therapy.[52] Alemtuzumab reduced relapses and MRI lesions compared to interferon β-1a subcutaneously, but had similar rates of disability progression; 77% of patients taking alemtuzumab were completely relapse-free at 2

years.[53] One long-term study saw benefits sustained from alemtuzumab over 5 years.[51]

ANTI-CD20 ANTIBODIES

Ocrelizumab and ofatumumab are monoclonal antibodies that target CD20-positive cells. Cells that express CD20 include B-cell precursors, mature B cells, and a subpopulation of T cells.[54] Ocrelizumab works rapidly, reducing the number of active lesions on MRI and the number of relapses by the fourth week of treatment.[55] Like alemtuzumab, ocrelizumab and ofatumumab are immune reconstitution therapies. Treatment with ocrelizumab reduced annualized relapse rates, disability progression, and number of MRI lesions compared to interferon-β.[56,57] Compared to teriflunomide, ofatumumab decreases relapses, prevents worsening disability, and decreases new or enlarging lesions on MRI.[58]

β-INTERFERONS

β-Interferons are thought to work by suppressing T-cell activity, downregulating antigen presentation by MHC class II molecules, decreasing adhesion molecules and matrix metalloproteinase 9, and increasing anti-inflammatory cytokines while decreasing pro-inflammatory cytokines.[59,60] There are two types of interferon-β (interferon β-1a and interferon β-1b) and a total of four preparations available to treat MS.[61–64] Placebo-controlled trials of each of the interferon-β agents have shown a reduced number of relapses and decreased disease progression measured on the EDSS in patients treated with interferon versus those who were given placebo.[65]

Data are available for patients who have been treated with interferon β-1b for up to 16 years. A sustained reduction in relapse rate of 40% was seen in patients who received the drug continuously, an improved response compared with those who received placebo or interferon only for a short time. Patients who received continuous interferon therapy also had slower rates of disease progression.[66,67] Eight-year follow-up data for interferon β-1a given intramuscularly did not show this sustained reduction in

relapse rate but did show that those who began treatment earlier had better long-term outcomes.[66]

CLADRIBINE

Cladribine was initially approved for hematologic malignancies, but has been repurposed as a treatment for relapsing-remitting MS. Like alemtuzumab and the anti-CD20 antibodies, it is an immune reconstitution therapy.[52] Its probable mechanism of action in MS is depletion of B and T lymphocytes.[68] Cladribine may also prevent activation of T cells.[68] Regulatory B and T cells increase fairly rapidly, but memory B cells and some T helper cells are at low levels at least 24 months after beginning treatment.[69] This extended action of cladribine has led to a pulsed dosing schedule of two doses per year for 2 years.[70] Cladribine decreased annualized relapse rate by about half compared to placebo, and almost 80% of patients treated with cladribine were relapse-free at 96 weeks.[71] Patients treated with cladribine also had fewer lesions on MRI and decreased progression of disability.[71] These improvements were sustained for at least two additional years beyond the end of the study.[72]

FUMARATES

Dimethyl fumarate and diroximel fumarate are rapidly cleaved in the intestine to form their active forms, monomethyl fumarate. All three agents, dimethyl fumarate, diroximel fumarate, and monomethyl fumarate, are now on the market for treatment of MS. Monomethyl fumarate causes a shift in cytokine production from interferon-γ and tumor necrosis factor-α to interleukin-4 and -5[73] and alterations of the subpopulations of B and T cells.[74] Dimethyl fumarate also activates the antioxidant effects of nuclear 1 factor (erythroid-related 2)-like 2 (Nrf2) transcriptional pathway that may prevent the neurodegeneration in MS by decreasing oxidative damage.[73,74] Dimethyl fumarate reduces the relapse rate by about half and new lesion development on MRI scan compared to placebo.[75]

GLATIRAMER ACETATE

Glatiramer acetate decreases type-1 helper T (T_H1) cells while increasing type-2 helper T (T_H2) cells. Additionally, it increases production of nerve growth factors.[60] The short-term and long-term efficacy of glatiramer acetate is similar to that of the interferons.[65]

MITOXANTRONE

Mitoxantrone works as a general immunomodulator. It decreases monocytes and macrophages and inhibits T and B cells.[76] Compared with placebo, mitoxantrone decreased the number of exacerbations and improved MRI in treated patients.[76]

NATALIZUMAB

Natalizumab is a humanized monoclonal IgG4 antibody. It blocks T-cell entry into the CNS by binding to $\alpha_4\beta_1$-integrin located on the lymphocyte to keep it from binding to the vascular cell adhesion molecule-1 on the endothelial cell.[77] In clinical trials, natalizumab was very effective, reducing the 1-year relapse rate by 68%, the risk of progression of disability in 2 years by 42%, and new lesions on MRI by 83%.[76]

S1P-RECEPTOR MODULATORS

Fingolimod, ozanimod, ponesimod, and siponimod are S1P-receptor modulators. They bind to the S1P receptor 1 expressed on T cells.[29] This binding causes the receptor to be internalized in the T cell, where it is unresponsive to the normal signal that causes the T cell to exit the lymphoid tissues and recirculate.[29] Without the T cells circulating, they are not activated, which disrupts the inflammatory cycle. There are different S1P receptor subtypes (1–5). Fingolimod binds to S1P receptor subtypes 1, 3, 4, and 5; ozanimod and siponimod bind to S1P receptor subtypes 1 and 5.[78,79] Fingolimod has been shown to decrease the relapse rate by about half compared with placebo as well as to reduce disability progression.[80] Ozanimod reduced active brain lesions within 6 months compared to placebo.[81] Ozanimod decreased the relapse rate and the number of new MRI lesions, but not disability progression compared to

interferon β-1a at 12 or 24 months.[82,83] Siponimod decreased new MRI lesions as quickly as 3 months compared to placebo and sustained this effect for up to 2 years.[79] Siponimod was also compared to placebo for secondary-progressive MS. It decreased disability progression at 6 months, decreased lesions in the brain, and decreased relapse rate by about half.[84]

TERIFLUNOMIDE

Teriflunomide is the active metabolite of leflunomide. It is thought to act in MS by blocking de novo pyrimidine synthesis, inhibiting B- and T-cell division, and blocking the inflammatory pathway prominent in MS.[85] It may also inhibit the pairing of T cells and APC to prevent T-cell activation. Teriflunomide reduces the annualized relapse rate by about 20% to 30% and reduces the risk of new MRI lesions by 60% to 80% compared to placebo in clinical trials.[85]

Treatment of Progressive Forms of Multiple Sclerosis

Patients with both secondary-progressive and primary-progressive MS may experience relapses. In these cases, all of the agents used for relapsing-remitting MS may be useful to reduce the number of relapses.[86] Some evidence suggests that therapies (specifically, interferon β-1a) are less effective for relapses in secondary-progressive MS than for relapsing-remitting MS.[86] This finding is consistent with the known mechanisms of action for the currently available agents, which are directed at the inflammatory processes. Siponimod has demonstrated benefit in secondary-progressive MS compared to placebo.[84] Treatment for primary-progressive MS are even more sparse, with secondary data analysis showing no effect for most drugs.[87] Ocrelizumab is the only FDA-approved medication for primary-progressive MS. It improved disability progression and decreased lesions on MRI compared to placebo at 24 weeks.[88]

Symptom Management

As disability increases, many patients with MS exhibit other associated symptoms that require targeted treatment (see **Table 57-2**).

BLADDER, BOWEL, AND SEXUAL DYSFUNCTION

Bladder, bowel, and sexual dysfunction are very common in patients with MS. Up to 90% of patients have bladder symptoms; constipation or bowel incontinence occur in ~50% of patients; and sexual dysfunction occurs in 50% to 90% of males and 40% to 80% of females.[41,43] It is also known that those patients with more bladder symptoms or sexual dysfunction have lower quality of life compared with patients without these problems.[41] The treatment approaches for these disorders in MS are similar to those used when these symptoms occur as part of a primary disorder.

IMPAIRED AMBULATION

Up to 90% of patients with MS stated that they had some limitation to their walking ability within 10 years of diagnosis.[42] Physical therapy and conditioning may be of some help for this problem.[42,89] Another approved treatment option is extended-release dalfampridine. This agent blocks potassium channels and prevents repolarization of the cell, thus prolonging action potentials and nerve impulse transmission in the demyelinated axon.

In clinical studies of extended-release dalfampridine, 57% of treated patients were unable to decrease the amount of time it took them to walk 25 feet. The 43% who did decrease their time were considered responders. On average, they improved their speed to walk 25 feet by 25% (~3 seconds faster).[42] Clinically, it may be difficult to determine which patients respond well to extended-release dalfampridine without conducting timed 25-foot walks.[42] Patients self-reported improvement when extended-release dalfampridine was compared to placebo.[42] In those patients who respond, the effect appears to be sustained for at least 2 years.[90]

Adverse effects associated with extended-release dalfampridine include urinary tract infections, insomnia, dizziness, headache, and nausea. Seizures are a less common adverse effect and are related to dose and use of immediate-release dalfampridine. Therefore, this agent is contraindicated in patients with a history of seizures.[91]

PAIN

Between 30% and 90% of patients with MS report experiencing pain.[43] Pain related to MS is of two types: non-neurogenic and neurogenic. Non-neurogenic pain is often related to paralysis, immobility, or spasticity; examples include tension-type headache, low back pain, and limb pain associated with poor mobility or postural changes.[92] Physical therapy, repositioning limbs, and typical analgesics may be effective for treatment of non-neurogenic pain.

A number of painful neurogenic conditions have been described in association with MS (**Table 57-3**).[92] Patients often describe neurogenic pain as having a burning, aching, pricking, stabbing, or smarting quality. Atypical analgesics are used for neurogenic pain. For trigeminal neuralgia, carbamazepine and oxcarbazepine are first-line treatments.[92] Baclofen, lamotrigine, gabapentin, topiramate, or nabiximols may be helpful as second-line treatments.[92] Surgical options may provide relief if drug treatments are ineffective.[92] Antiepileptic medicines and antidepressants are also commonly used for other types of neurogenic pain.

Table 57-3
Types of Neurogenic Pain Associated With Multiple Sclerosis

Trigeminal neuralgia—sudden, usually unilateral, severe, brief, stabbing, recurrent episodes of pain in the distribution of one or more branches of the trigeminal nerve
Lhermitte phenomenon—sudden onset, brief, electric shock-like sensation traveling rapidly down to the spine or into the arms or legs. Usually caused by flexing the neck. Sometimes occur occasionally for short periods
Tonic spasms
Burning dysesthesia of the limbs and trunk

Migraine headache

Source: Chisari CG, Sgarlata E, Arena S, D'Amico E, Toscano S, Patti F. An update on the pharmacological management of pain in patients with multiple sclerosis. *Expert Opin Pharmacother*. 2020;21:2249–2263.

FATIGUE

Often described as the most disabling symptom by patients with MS, 74% experience fatigue.[43] The reason that patients exhibit fatigue is not well understood; however, hypotheses include direct effects of cytokines, axonal loss, or cortical disorganization.[44] Conduction is impaired in demyelinated axons, and increases in temperature may further worsen conduction.[44] However, fatigue may be caused or worsened by other mechanisms such as sleep dysfunction, depression, or medication adverse effects.[43]

Nonpharmacologic approaches are often the mainstay of therapy for fatigue and may include interventions to improve sleep quality, treatment for depression when present, improvements in diet, and increased physical activity.[43,93] Cognitive behavioral therapy has been helpful for some patients.[94] Cooling therapy with jackets worn over large areas of the body has demonstrated benefit in clinical trials.[95]

The only pharmacologic therapy for fatigue with proven benefit is amantadine; however, the clinical trials for this agent have included small numbers of patients.[43] Sustained-release fampridine may be helpful in some patients.[43] Modafinil has been used in two placebo-controlled studies, but neither trial showed significant differences in response between modafinil and placebo.[43]

COGNITIVE DYSFUNCTION

Cognitive dysfunction may occur early in the course of the disease and has a negative impact on quality of life.[96] Among patients with CIS, 29% had cognitive impairment at the time of presentation. In this study, the only predictor of cognitive impairment was the number of lesions on MRI.[96] Between 40% and 70% of MS patients eventually have some cognitive dysfunction.[43] Another study

followed patients diagnosed with CIS and determined that lower levels of vitamin D and smoking in the 2 years following MS diagnosis predicted worse cognitive functioning 11 years later.[97] The most common problems are memory impairment, slowed speed of information processing, decreased mental flexibility, and impaired executive functioning.[43] Cognitive dysfunction can also limit the ability of patients with MS to understand discussion of disease and treatments.[96] Breaking down discussions into various components (eg, intended effects, adverse effects) helps with understanding.[96]

Nonpharmacologic interventions such as cognitive rehabilitation to develop the use of intact cognitive skills to compensate for areas of poor cognitive performance may be beneficial.[96] Treatment of MS with immunomodulatory drugs has shown some benefit for cognitive impairments.[97,98] In several small studies, dalfampridine treatment improved several indicators of cognitive function: processing speed, psychomotor speed, attention, alertness, planning, and fluency.[99–101] Additionally, a meta-analysis of acetylcholinesterase inhibitors and stimulants did not show cognitive benefit for patients with MS.[102] One small study of high-dose simvastatin was promising[103] and another small study of vitamin D replacement in patients with deficient serum 25-hydroxyvitamin D concentrations improved cognitive performance.[104]

SPASTICITY

Spasticity can be defined as an increased resistance of muscle to an externally imposed stretch.[45] Approximately 60% of patients with MS exhibit spasticity, which may worsen with other noxious stimuli such as a full bladder or colon, infection, or MS exacerbations.[43,45] Complications from spasticity may include pain, spasms, reduced mobility, limited range of movement, contractures, fatigue, poor quality of sleep, cardiopulmonary deconditioning, decubitus ulcers, and skin breakdown.[45]

Nonpharmacologic therapies, such as repositioning physical therapy, stretching, or splinting, may help with spasticity.[45] These efforts are usually most successful with spasticity that is localized to

one area of the body. Injection of intramuscular botulinum toxin can also be beneficial for localized spasticity.[45] Spasticity that is generalized to many areas of the body is best addressed with systemic therapy in addition to nonpharmacologic treatments. Baclofen and tizanidine are first-line therapies for spasticity. Gabapentin, benzodiazepines, and dantrolene are considered as second-line agents.[45] In severe cases, intrathecal baclofen can be delivered via infusion pump through a catheter into the intrathecal space.[45] A combination of tetrahydrocannabinol and cannabidiol oromucosal spray has shown some benefit for spasticity for patients with MS, but trials have been small.[105–107] There is no FDA-approved indication for this use in the United States.

PSYCHIATRIC DYSFUNCTION

Psychiatric problems, including depression, bipolar disorder, pseudobulbar affect (emotional lability), anxiety, and psychosis, all occur at increased rates in patients with MS compared with the general population.[46] Depression can affect up to 50% of patients with MS.[43] Several clinical trials of depression treatment have been conducted in patients with MS. In these, cognitive behavioral therapy has been shown to be effective, and fluoxetine, desipramine, paroxetine, and sertraline have been shown to have benefit in some trials.[46,108]

Pseudobulbar affect occurs in ~10% of patients with MS and involves frequent and inappropriate episodes of crying, laughing, or both, which may be unrelated to underlying mood. The exact cause of pseudobulbar affect is not known, but it may be caused by disruption of neural pathways from the brainstem and cerebellum. Serotonin, dopamine, and glutamate also appear to be important in the development of pseudobulbar affect. It is not isolated to patients with MS but may also occur in other neurologic disorders such as stroke. This disorder can be socially stigmatizing and highly disabling.[109]

When used together, dextromethorphan and quinidine have shown efficacy for pseudobulbar affect, and a combination product is

approved for this indication by the FDA. Dextromethorphan is an agonist at σ-1 receptors, suppressing release of excitatory neurotransmitters, and an antagonist at *N*-methyl-D-aspartate glutamate receptors.[109] Dextromethorphan is metabolized by CYP 2D6 to dextrorphan, which does not cross the blood–brain barrier. When a low dose of quinidine, a CYP 2D6 inhibitor, is added, dextromethorphan serum concentrations are increased 20-fold. In a 12-week study of 283 patients, a 49% improvement in inappropriate emotional episodes was demonstrated.[109]

Vitamin D

Although early clinical trials with vitamin D appeared to benefit patients with MS,[8] other studies did not find benefits.[8,110–112] A larger clinical trial is ongoing to evaluate the therapeutic potential of vitamin D supplementation in patients with MS.[113]

CASE 57-1

QUESTION 1: C.B. is a 32-year-old female of Finnish descent who presents to the neurology clinic with slurred speech and double vision. These symptoms began a week ago and have not changed. C.B. saw her primary care physician at that time, who referred her to the neurology clinic. Her past medical history is unremarkable other than a normal gestation and vaginal delivery of a female infant 3 years ago. Today, her vital signs are a blood pressure of 126/82 mm Hg, heart rate of 78 beats/minute, respirations at 20 breaths/minute, and a temperature of 99.32 °F (37.4 °C). Review of systems is negative, except as noted above. On neurologic examination, C.B. is alert and her speech is fluent, but slurred. Her cranial nerves examination reveals sixth nerve palsy, and C.B. cannot abduct the right eye on rightward gaze; her visual fields are full. Her tongue and palate are at midline and there is no facial asymmetry. Her motor examination reveals normal tone and strength; her sensory examination is intact to light touch, pinprick, vibration, and position sense. Her finger-to-nose, rapid alternating movements, heel-to-shin, and gait are all normal. On MRI, C.B. has one gadolinium-enhancing lesion in the right mid-pons. Examination of her CSF reveals the following:

Red blood cells, 0 (normal 0)
White blood cells, 0 (normal 0–5)

Protein, 24 mg/dL (normal 15–50 mg/100 mL)
Glucose, 60 mg/dL (normal 50–80 mg/100 mL)

Her CSF is positive for oligoclonal bands, and immunoglobulin G (IgG) synthesis rate is 4.3 mg/24 hours (normal <3.3 mg/24 hours). Her current medications include a multivitamin one by mouth (PO) every morning, loratadine 10 mg PO every morning, and levonorgestrel-releasing intrauterine system.

What risk factors, signs, and symptoms suggestive of MS are present in C.B.? How do her MRI and CSF findings support or refute a diagnosis of MS?

C.B. has several epidemiologic factors associated with MS (see **Table 57-1**). She is 32 years old, consistent with onset between the ages of 20 and 50 years; she is female—females are two to three times more likely to develop MS than males—and she is of northern European ancestry, which also increases her risk of MS. Her symptoms and physical examination findings are consistent with a demyelinating event in the pons area of the brainstem. On MRI, C.B. has one active (gadolinium-enhancing) lesion in this area. This finding on the MRI is abnormal, and gadolinium-enhancing lesions are found commonly in patients with MS. Her CSF examination on lumbar puncture shows the presence of oligoclonal bands and an increased rate of IgG synthesis. These findings are also consistent with a diagnosis of MS. Although the combined evidence from her history, examination, and MRI studies make the eventual diagnosis of MS likely, they do not demonstrate dissemination in space and time. The criteria for dissemination in time is met by the presence of oligoclonal bands. To show dissemination in space, another clinical event affecting another part of the body or another MRI showing lesions in a different area of the brain would be necessary.[1] At the present time, C.B. would be diagnosed as having CIS.

Case 57-1, Question 2: Should C.B. begin treatment at this time? If so, what treatment(s) would be appropriate?

Cladribine, glatiramer acetate, interferon-β preparations, ozanimod, siponimod, and teriflunomide have demonstrated reduced

development of MS if taken after the identification of CIS.[114,115] Further, there is evidence that earlier treatment with a disease-modifying regimen delays conversion to clinically definite MS compared to delaying treatment.[116–118] C.B. should be educated on the risk of developing clinically definite MS, and she should begin therapy with one of these agents. There is no evidence on which to base the choice of therapy; commonly the prescriber will have a preference based on discussion with the patient. However, the FDA does not recommend cladribine for CIS therapy based on its safety profile.[70]

CASE 57-1, QUESTION 3: C.B. is started on glatiramer acetate 20 mg subcutaneously daily. How should C.B. be counseled regarding the injection of glatiramer acetate and the potential adverse effects of this treatment? How can she help alleviate or avoid these adverse effects? What monitoring is required?

Glatiramer acetate is supplied as a single-use, prefilled syringe. In general, the recommended administration techniques are similar to those used for other subcutaneously administered products, and the important counseling points are summarized in **Table 57-4**. The administration technique is slightly different for the intramuscular injection. There are product-specific differences in dose preparation for which it is important to consult the product information. C.B. should be instructed on administration technique, and it is recommended that the first injection be self-administered under the supervision of a health care professional.

Table 57-4
Patient Counseling Points for β-Interferon and Glatiramer Acetate Products

For All Products
Use clean technique—wash hands with soap and water, clean injection site with an alcohol swab, do not touch site or needle tip to other surfaces or with fingers.
Choose an appropriate site:

For subcutaneous injection—fleshy part of upper back, arm, front of thighs, lower abdomen, fleshy area of upper hip For intramuscular injection—front of thigh, side of thigh, upper arm
Rotate between injection sites to avoid overuse of any one site.
Examine the reconstituted product for particles, cloudiness, or color changes. The products should be colorless to light yellow.
For subcutaneous injection—pinch up a fold of skin between index finger and thumb for the injection. For intramuscular injection—stretch the skin between index finger and thumb for the injection.
Insert the needle at a 90 degree angle to the skin.
Release the skin.
Steadily push down on the plunger until all the medicine is injected.
Pull needle straight out of skin and dispose of it in a hard-walled plastic container.

Sources: Betaseron (interferon beta-1b). Package insert. Bayer HealthCare Pharmaceuticals; 2020; Rebif (interferon beta-1b). Package insert. EMD Serono; 2020; Avonex (interferon beta-1a). Package insert. Biogen Inc.; 2020; Plegridy (peginterferon beta-1a). Package insert. Biogen Inc.; 2020; Copaxone (Glatiramer Acetate Injection). Package insert. Teva Neuroscience; 2019.

Glatiramer acetate is initiated at a dose of 20 mg subcutaneously daily or 40 mg three times weekly.[119] No dosage titration is required. However, for interferon-β products, a product-specific titration schedule is recommended to minimize flu-like symptoms.[61–64]

Common adverse effects of glatiramer acetate are injection site reactions and post-injection systemic reactions.[119] Injection site reactions with glatiramer acetate include hemorrhage, hypersensitivity, inflammation, mass, pain, edema, and atrophy at the injection sites. Rarely, necrosis at the injection site can develop. Lipoatrophy may be seen in up to 45% of patients with longer-term use.[119] Acute injection site reactions may be reduced by applying warm compresses or ice to the injection site before injection, warming the medication to room temperature before injection, and ensuring that the needle completely penetrates the skin during injection.[120,121] Symptoms of post-injection systemic reactions include facial flushing, chest tightness, dyspnea, palpitations, tachycardia, and anxiety.[119] Approximately 16% of patients experience this

reaction. When this reaction occurs, its onset is within seconds to minutes after injection, and it may last up to 60 minutes.[119] No specific treatment is recommended for post-injection systemic reactions to glatiramer acetate.

Adverse effects are fairly common with interferon-β; they include leukopenia (36%–86%), injection site reaction (6%–92%) and necrosis (3%–6%), flu-like symptoms (49%–57%), breakthrough menstrual bleeding (28%), and increased liver function tests (12%–27%).[61–64,122] Depression and suicide are seen in patients treated with the β-interferons; however, it is difficult to distinguish the independent contribution of interferon from any possible concomitant effects of MS itself.[123]

Flu-like reactions include the symptoms of fever, chills, myalgia, malaise, and sweating, and they occur in about half of patients who are initiated on an interferon-β.[60] Symptoms usually begin 3 to 6 hours after administration and last ~24 hours. Female patients and those with lower body mass index may have more severe flu-like symptoms.[122] Most patients find that these symptoms decrease with time, with only 10% of patients reporting flu-like symptoms after 1 year of therapy.[60] Helpful tips for patients to reduce flu-like symptoms include administering the injections at night to sleep through the time of peak symptoms, taking ibuprofen or acetaminophen before and every 4 to 6 hours as needed after the injection, and gradual titration to full dose.[122,123]

Injection site reactions vary from 92% with some subcutaneous preparations of interferon-β to 6% with the intramuscular preparation.[61–64] These symptoms are similar to those seen with glatiramer acetate except, that lipoatrophy is not seen with interferon-β. Females appear to be more likely to experience injection site reactions than males.[122] Strategies to reduce injection site reactions include injecting the drug in areas with more subcutaneous fat (abdomen or buttocks), rotating injection sites, using an auto-injection device, and icing the site after injection.[122,123]

General monitoring recommendations for both interferon-β and glatiramer acetate include observation of injection sites for infection, necrosis, and atrophy. Specifically for the β-interferons, complete

blood counts and liver function tests are monitored.[61–64] The frequency of monitoring is not specified in product literature, but a reasonable approach would be at baseline and 1 to 3 months after initiation and then every 6 to 12 months during continuation of therapy. Additionally, patients should be monitored for signs or symptoms of depression. Therefore, the specific counseling and monitoring plan needed for C.B. is instruction in self-injection technique for the subcutaneous injection and discussion of injection site reactions, including their prevention and monitoring, and post-injection systemic reactions. C.B. should also be counseled regarding the value of ongoing clinical monitoring (for efficacy, injection site reactions, and post-injection reactions) during glatiramer acetate therapy.

Case 57-1, Question 4: Six months later, C.B. returns for an appointment with her neurologist. During the discussion, she states that she is not having any problems with injection technique or adverse effects, but she reveals that she is only using the glatiramer acetate three or four times a week instead of the daily injection schedule that was prescribed. When questioned, she states, "I just don't know that it's doing anything." How might C.B.'s neurologist deal with this adherence problem?

Adherence is often poor with disease-modifying therapy for MS; over 2 to 5 years, only 60% to 76% of patients adhere to therapy.[124] Patient characteristics and other factors that have been associated with poor adherence are listed in **Table 57-5**.[124–130] In one study, self-efficacy and belief that the medicine would have benefit were strong predictors of adherence, whereas cognitive difficulties, occurrence of adverse effects, depression, more disability, and poor quality of life predicted nonadherence.[131] In another interesting study among patients who had discontinued treatment against medical advice, 42.3% were found to be using avoidance coping strategies by avoiding engaging in care or rationalizing their decision to not use treatment such as exaggerated skepticism about medication effectiveness, irrational concerns about treatment, or unrealistic optimism about the projected course of MS.[129] Adherent patients

have a lower risk of relapses, fewer emergency department visits, and fewer hospitalizations.[132,133]

Table 57-5

Patient Characteristics and Other Factors Associated With Reduced Adherence to Therapies

For All Therapies	Specific to a-Interferons or Glatiramer Acetate
Younger age	Secondary-progressive multiple sclerosis
Female sex	Cognitive impairment
Perceived lack of efficacy	Depression
Unrealistic expectations	Lifestyle or economic instability
Inpatient stay in previous year	Needle phobia
More than two relapses in previous year	Lack of family or other support
Out of pocket costs	
Mild disease course	
Adverse effects	
Inconvenience	
Avoidance coping (avoiding engaging in care, rationalizing decision to not take therapy)

of adherence to interferons in the treatment of multiple sclerosis: a non-experimental, retrospective, cohort study. *Clin Drug Investig*. 2010;30:89–100.

For C.B., it appears that she has perceived lack of efficacy for the glatiramer acetate; however, other factors associated with nonadherence should be sought and discussed with her. For an individual patient, it is impossible to know what the course of disease would be without treatment; thus, many patients believe that the medicine is not having a positive impact. Particularly for a patient with CIS who does not have ongoing symptoms, embarking on a lifelong therapy can be challenging. Additionally, there is no immediate feedback to the patient that the medication is having an effect, in contrast to some other diseases such as diabetes in which a fingerstick blood glucose measurement provides positive reinforcement.[125] Some evidence suggests that patients would prefer not to take a treatment that causes significant adverse effects until the symptoms experienced from their MS are worse than the perceived adverse effects.[134,135] Strategies that may improve adherence include establishing a good patient–health care provider relationship, patient education and periodic reinforcement, management of adverse effects, involving care partners, treating depression, and motivational interviewing/cognitive behavioral therapy.[125,129]

CASE 57-1, QUESTION 5: After re-education and frank discussion, C.B.'s adherence improves, and she does well for a year on glatiramer acetate therapy. However, a routine monitoring MRI scan shows a new gadolinium-enhancing lesion on her right optic nerve. Additionally, a new nonenhancing lesion is apparent on the MRI scan. Does this new information change her diagnosis and treatment?

With these new MRI lesions, the "separation in space and time" criteria for the diagnosis of MS have been met. Thus, C.B. now would be diagnosed with MS. Given her history, she is diagnosed with relapsing-remitting MS. To guide the clinician in choosing the most efficacious therapy, there are data from several clinical trials that directly compare first-line therapies (see **Table 57-**

6).[53,58,75,82,83,136–142] From the data available, it appears that interferon β-1a intramuscularly once weekly is less effective than the other first-line treatments. There is emerging evidence that some therapies (eg, alemtuzumab, ofatumumab, and ozanimod) are more efficacious than some older medicines.[53,58,82,83,142]

Table 57-6
Clinical Trials Directly Comparing Active Treatments

Trial	Treatments	Results
INCOMIN[136]	Interferon β-1b 250 µg subcutaneously every other day versus interferon β-1a 30 µg IM weekly	Compared with patients treated with interferon β-1a, more patients treated with interferon β-1b were relapse-free (51% vs 36%), there were fewer mean relapses (0.38% vs 0.5%), and fewer patients progressing 1 point on the EDSS (13% vs 30%) after 2 years.
EVIDENCE[137]	Interferon β-1a subcutaneously 44 µg three times weekly versus interferon β-1a 30 µg IM weekly	Compared with patients treated interferon β-1a IM, patients treated with interferon β-1a subcutaneously had fewer mean relapses (0.29% vs 0.4%) and fewer lesions on MRI after 24 weeks.
REGARD[138]	Interferon β-1a 44 µg subcutaneously three times weekly versus glatiramer acetate 20 mg subcutaneously daily	No significant differences in time to first relapse or MRI changes after 96 weeks.
BEYOND[139]	Interferon β-1b 250 µg subcutaneous every other day versus interferon β-1b 500 µg subcutaneous every other day versus glatiramer acetate 20 mg subcutaneous daily	No differences in relapse rate, EDSS progression, or MRI lesions after 2–3.5 years.

Trial	Treatments	Results
CONFIRM[77]	Dimethyl fumarate 240 mg PO twice daily versus dimethyl fumarate 240 mg PO three times daily versus glatiramer acetate 20 mg subcutaneous daily versus placebo	Compared to placebo, all active therapies reduced annualized relapse rates (0.22, 0.20, 0.29 vs 0.40), EDSS progression, and MRI lesions. No differences between dimethyl fumarate 240 mg twice daily and glatiramer for any outcome except for one type of MRI lesion after 2 years.
TENERE[140]	Teriflunomide 7 mg PO daily versus teriflunomide 14 mg PO daily versus interferon β-1a 44 µg subcutaneous three times weekly	No differences in relapse rate, treatment failure after 48 weeks.
CARE-MS I[53]	Alemtuzumab 12 mg IV daily for 5 days, then 12 mg IV daily for 3 days 12 months later versus interferon β-1a 44 µg subcutaneous three times weekly	More patients taking alemtuzumab were relapse-free (78%) at 2 years than the interferon group (59%). Fewer patients taking alemtuzumab had disease progression (8% vs 11%).
CARE-MS II[141]	Alemtuzumab 12 mg IV daily for 5 days, then 12 mg IV daily for 3 days 12 months later versus interferon β-1a 44 µg subcutaneous three times weekly	More patients taking alemtuzumab were relapse-free (65.4%) at 2 years than the interferon group (46.7%). Fewer patients taking alemtuzumab had disease progression (12.71% vs 21.13%). Fewer patients taking alemtuzumab had new MRI lesions (9% vs 23%).

Trial	Treatments	Results
ASCLEPIOS I/ASCLEPIOS II[58]	Teriflunomide 14 mg PO daily versus ofatumumab 20 mg subcutaneous days 1, 7, 14 and every 4 weeks	Annualized relapse rates were lower in the ofatumumab group (0.11) than the teriflunomide group (0.22). Patients with worsening disability was less with ofatumumab (10.9%) than teriflunomide (15%) at a mean follow-up of 1.6 years. The mean number of MRI lesions/scan was also less in the ofatumumab group.
RADIANCE[82]	Ozanimod 0.5 mg PO daily versus ozanimod 1 mg PO daily versus interferon β-1a IM 30 µg weekly	Annualized relapse rates were lower with ozanimod 0.5 mg (0.22) and 1 mg (0.17) compared to interferon (0.28). New MRI lesions were lower with both ozanimod groups. There was no difference in disability progression after 24 months.
SUNBEAM[83]	Ozanimod 0.5 mg PO daily versus ozanimod 1 mg PO daily versus interferon β-1a IM 30 µg weekly	Annualized relapse rates were lower with ozanimod 0.5 mg (0.24) and 1 mg (0.18) compared to interferon (0.35). New MRI lesions were lower with both ozanimod groups. There was no difference in functional scores or quality of life after at least 12 months of treatment.

EDSS, Expanded Disability Status Scale; IM, intramuscular; MRI, magnetic resonance imaging; PO, orally; IV, intravenous.

Case 57-1, Question 6: C.B. admits that she disliked giving herself daily injections and began therapy with dimethyl fumarate delayed-release 120 mg PO twice daily for 7 days, then 240 mg PO twice daily thereafter. What counseling should she receive regarding the adverse effects of this medication?

Dimethyl fumarate commonly causes flushing and gastrointestinal (GI) adverse effects; it has been formulated as a delayed-release product to help with these problems. Flushing occurs in about 30% to 38% of patients taking dimethyl fumarate in clinical trials.[75,143] The GI adverse effects include diarrhea 13%, nausea 11%, and upper abdominal pain 10%.[75,143] Taking doses with food helps decrease

both of these types of adverse effects. In a small study specifically examining flushing and GI effects, the incidence of flushing was much higher, up to 98% in some groups, but decreased somewhat with continued use. Each event lasted between 1 and 2 hours. Aspirin 325 mg taken 30 minutes prior to the dose decreases the incidence of flushing by about 14%. The subjects also had much higher incidences of GI effects, between 79% and 81%, falling to 53% to 61% during the second month of use. GI event onset was a median time of 2 weeks. Aspirin had no effect on GI symptoms.[73] Metoclopramide, ondansetron, domperidone, antacids, H_2-receptor antagonists, proton pump inhibitors, and antidiarrheals have been recommended to combat the GI symptoms, and antihistamines have been used for flushing but no testing of these approaches has been performed.[73] Use of diroximel fumarate may also decrease GI effects,[144] but use of monomethyl fumarate may not.[145] Lymphopenia occurs in about 2% of patients taking dimethyl fumarate; however, mean lymphocyte count decreases by about 30% in the first year of treatment and then stabilizes. Patients should have a complete blood count at baseline and then annually.[143]

C.B. should be counseled to take her doses with food. Because it is a delayed-release product, she should swallow the capsules whole. If she experiences flushing, aspirin 325 mg PO 30 minutes prior to dosing could be recommended. If she experiences GI problems, those could be treated symptomatically.[73]

Case 57-1, Question 7: C.B. continued on therapy with dimethyl fumarate. However, 1 year later, she has experienced one relapse and is currently hospitalized with another. She has been adherent to therapy. Her MRI shows several new gadolinium-enhancing lesions. What therapy should be recommended for acute treatment of C.B.'s current relapse? Would you change her maintenance therapy at this time?

Corticosteroids should be used to decrease the time to recover from acute relapses. The most commonly used regimen is 500 to 1000 mg intravenous methylprednisolone daily for 3 to 5 days with or without a subsequent regimen of tapering dose oral steroids for 1 to

3 weeks.[146] Comparison of oral and intravenous corticosteroid treatment shows that there are no major differences in clinical outcomes, and both treatments appear to be equally effective and safe.[50] A commonly recommended oral corticosteroid regimen is prednisone 1250 mg daily every other day for five doses.[146] Some investigators have attempted to use corticosteroids on a chronic basis, giving pulse doses of one or several days monthly; however, this type of regimen does not affect disability progression and should not be recommended.[147] Because C.B. is already hospitalized, she should receive methylprednisolone 1000 mg intravenously daily for 3 days. If she were an outpatient, either intravenous or oral steroid therapy could be recommended, but an oral corticosteroid regimen would be more convenient.

As MS therapies have become more effective, tolerance for relapses has decreased. No evidence of disease activity (NEDA) is a composite measure that indicates that there are (a) no new or enlarging T2-weighted lesions on MRI, (b) no new gadolinium-enhancing lesions on MRI, (c) no relapses, and (d) no progression on EDSS scores over a period of time.[148] Percentages of patients in clinical trials achieving NEDA status are between 28% and 45% over the first 2 to 3 years of therapy; however, this number may decrease over time.[148]

It appears that C.B. is failing treatment with dimethyl fumarate because she has experienced two relapses within ~1 year and has substantial new lesion formation on MRI; there are several alternatives at this point. C.B. should change to another therapy. A careful discussion of the potential risks and benefits of each possible treatment will ensure that the patient is well educated on the options and that an appropriate selection is made.

Case 57-1, Question 8: After lengthy discussion, C.B. elects to discontinue dimethyl fumarate therapy and start fingolimod 0.5 mg PO daily. How should C.B. be counseled regarding the potential benefits and adverse effects of fingolimod? What monitoring will be necessary?

In studies of fingolimod, 70.4% of patients remained relapse-free for 2 years compared with 45.6% for those treated with placebo. At 1 year, 82.6% of fingolimod-treated patients were relapse-free compared with 69.3% of those treated with interferon β-1a intramuscularly. The annualized relapse rate was 0.16/year for fingolimod, 0.40/year for placebo, and 0.33/year for interferon β-1a intramuscularly.[80] C.B. should expect good suppression of her MS with fingolimod treatment.

Because S1P receptors are not confined to lymphocytes, adverse effects of S1P receptor modulators (fingolimod, ozanimod, ponesimod, and siponimod) may affect other body organs and tissues. For example, a transient, dose-dependent reduction in heart rate can occur within 1 hour after the first fingolimod dose (bradycardia in 1.3%); first- and second-degree atrioventricular block can also occur (0.1% and 0.2%, respectively).[80,115,149–151] Patients with pre-existing sinus bradycardia or heart block without pacemakers should not be given S1P receptor modulators. Sphingosine-1-phosphate receptor modulators may cause a small increase in blood pressure over time.[115,149–151] However, foods with large amounts of tyramine (>150 mg) could cause severe hypertension when given with ozanimod because an active metabolite of ozanimod inhibits monoamine oxidase type B.[115] Ozanimod, ponesimod, and siponimod have several other drug–drug interactions that require precautions.[115,150] Patients with CYP 2C9*3/*3 genotype should not be given siponimod because of substantially elevated plasma concentrations; dose decreases are needed with other genotypes.[150] Other adverse effects of S1P receptor modulators include macular edema and a reduction in forced vital capacity.[80] Macular edema occurs in <1% of patients who receive S1P receptor modulators; however, patients with a history of uveitis or diabetes have an increased risk.[80]

Because the mechanism of action of S1P receptor modulators is to prevent lymphocytes from circulating, there is a reduction in peripheral blood lymphocytes and an increase in infections and, possibly, cancers.[80] This reduction in peripheral blood lymphocytes is reversible within 4 to 8 weeks of discontinuation of fingolimod,[149] 30

days for ozanimod,[115] 10 days for siponimod,[150] and 1 week for ponesimod.[151] Sphingosine-1-phosphate receptor modulators do not inhibit humoral immunity to infections.[80] Progressive multifocal leukoencephalopathy (PML) has been reported in patients taking fingolimod.[149] PML is caused by JC DNA polyomavirus (JCV) reactivation. JCV then causes an infection of oligodendrocytes that is often fatal or causes permanent disability.[152] Dormant JCV infection is relatively common, with 50% to 86% of adults having antibodies to JCV. When a patient is immunosuppressed, JCV may become reactivated.[152] PML is rapidly progressive and has a mortality rate of ~50%.[152] Symptoms of PML include neurobehavioral, motor, language, and cognitive changes; seizures; vision changes; hemiparesis; and tremor.[152] Notably, all of these symptoms could be mistaken for an MS relapse. Other MS medications can cause PML. A drug risk classification scheme has been proposed for PML, which places natalizumab in class I (high risk); dimethyl fumarate and fingolimod in class II (low risk); and alemtuzumab, mitoxantrone, rituximab, and teriflunomide in class III (very low or no risk).[153] Some of the newer MS agents were not in use at the time this classification scheme was proposed. Of note, PML has been reported with cladribine and ofatumumab when used in oncology.[154,155] It would seem likely that ocrelizumab, ozanimod, ponesimod, and siponimod could also be associated with PML, and the risk is listed in prescribing information for these medicines.[115,150,151,156]

Increases in liver enzymes (transaminase and bilirubin) have also been observed with S1P receptor modulator treatment.[80] Because fingolimod has a long half-life of 9 to 10 days, its pharmacologic effects will still be present for up to 2 months after therapy is discontinued.[149] Ozanimod has a half-life of 21 hours, but the half-life of its active metabolite is 11 days, and effects may remain for up to 3 months after stopping treatment.[115] Siponimod has a shorter half-life of 30 hours, and most effects have dissipated within 10 days.[150] Ponesimod's half-life is 33 hours with most effects resolving in 1 to 2 weeks.[151] Baseline testing and continued monitoring recommended with the use of S1P-receptor modulators is summarized in **Table 57-7**. These agents should be given as monotherapy, and the patient

should not have had a relapse or have been treated with corticosteroids within 30 days of starting treatment. If patients do not have an existing history of varicella zoster infection or vaccination, vaccination should be undertaken before initiating therapy.[115,149–151] Live-attenuated vaccines should not be used while receiving S1P-receptor modulators, and it is not known how effective the body's response to other vaccination is during treatment.[115,150–152,157] Rates of varicella infections are between 7 and 11/1000 patient-years.[158] C.B. should wait for 30 days after her relapse and any corticosteroid treatment before starting fingolimod. During this time, she can have baseline testing before starting treatment. She should be educated on potential adverse effects and the long-lasting pharmacologic effects of fingolimod that may persist for up to 2 months after therapy is discontinued.

Table 57-7

Baseline Testing and Monitoring Associated With S1P Receptor Modulators

Baseline
Varicella zoster immunity evaluation and vaccination, if needed
Ophthalmology evaluation for macular edema
FEV_1 or full pulmonary function testing, if patient has history of asthma or chronic obstructive pulmonary disease
Pulse and blood pressure
Complete blood count
Liver function tests
Electrocardiogram
Fingolimod Only
Dermatologic evaluation for melanomas
Siponimod Only
CYP 2C9 genotype determination
Monitoring
Ophthalmology evaluation at 4 months and as needed thereafter
Complete blood count every 6 months
Liver function tests every 6 months
Dermatologic evaluation as needed
FEV_1 as needed

For All Patients Initiating Fingolimod and Patients Initiating Ponesimod and Siponimod With Certain Cardiac History

Observe in clinical area for 6 hours after initial dose with monitoring of blood pressure and pulse and repeat electrocardiogram at 6 hours post-dose

CYP, cytochrome P_{450}; FEV_1, forced expiratory volume in 1 second.

CASE 57-1, QUESTION 9: C.B. is appropriately started on fingolimod and does very well with visits to the neurologist every 6 months. When she is seen 2 years later, she informs her care providers that she is considering having another child. How should C.B. be counseled regarding fingolimod therapy during pregnancy?

It is well-documented that the rate of relapses for females with MS decreases during pregnancy, increases in the first 3 months after delivery, then returns to the prepregnancy rate.[159] No treatment for MS is recommended for use during pregnancy, and some therapies, such as cladribine and mitoxantrone, require pregnancy tests before each infusion. However, there are limited data regarding the exposure of fetuses to some of the treatments for MS when given during early pregnancy. No increase in spontaneous abortions or stillbirths was seen with glatiramer acetate or β-interferons.[159] However, very few of these exposures were for the full term of pregnancy. A report of 66 pregnancies in females taking fingolimod found fetal abnormalities in 7.6%. In all these cases, the exposure was in the first trimester.[159] Pregnancy is contraindicated during treatment with teriflunomide, with contraception required for both females and males.[160] Eighty-nine pregnancies (70 in females exposed to teriflunomide and 19 in partners of males exposed to teriflunomide) were reported during clinical trials. Of these, 42 healthy live births, 31 induced abortions, and 14 spontaneous abortions were reported. It should be noted that in almost all cases, teriflunomide was stopped and accelerated elimination procedures were undertaken as soon as the pregnancy was known to minimize

fetal exposure.[161] Alemtuzumab is also contraindicated during pregnancy. Females should use adequate contraceptive measures during treatment and for 4 months following treatment. Alemtuzumab can cause thyroid disorders, which, during pregnancy, can have serious adverse effects on the fetus.[162] Cladribine is contraindicated in pregnancy and lactation, and males taking cladribine should also prevent pregnancy.[70] Pregnancy should be avoided in females taking ocrelizumab and ofatumumab and for 6 months after discontinuing the drugs.[156,163]

In general, MS therapy should be discontinued before conception. In the case of C.B., she should be advised that she would need to discontinue fingolimod at least 2 months before conception and stay off the medication while pregnant. It is not known whether fingolimod is excreted into the breast milk of nursing females.[149] Because of the potential adverse effects of fingolimod on an infant's immune system, she should be advised either to not breast-feed or to abstain from taking fingolimod during nursing. Similar recommendations are in place for ozanimod and siponimod, but recommendations for length of time to avoid conception after discontinuation is different because of differences in elimination; 3 months for ozanimod, 10 days for siponimod, and 1 week for ponesimod.[115,149–151]

Case 57-1, Question 10: C.B. discontinued fingolimod, conceived ~4 months later, and delivered a healthy male child after a normal gestation and labor. She experienced a relapse of MS 2 months after delivery, discontinued nursing, and was treated with corticosteroids. Two months after the relapse and treatment, she returns to the neurology clinic for a follow-up appointment. She states that she is ready to restart fingolimod therapy at this time. She states that she is often very tired and feels that "she can't continue." However, she admits that this feeling may also be related to being a new mother. She states that her husband and daughter help significantly with care of the infant. She has noticed some jerkiness in her gait, and she states that sometimes her toes will contract toward her head involuntarily. Her neurologic examination shows spasticity in her lower extremities. What treatments would be appropriate for management of C.B.'s spasticity? How should her fatigue be addressed?

Nonpharmacologic therapy such as stretching may help with C.B.'s spasticity. Her symptoms are more generalized (involving the

lower extremities) than localized, so systemic therapy may be more beneficial than localized therapy such as splinting or botulinum toxin injections (therapies that might be considered if only her toes were involved).[43,45] Systemic therapies that may relieve spasticity include baclofen and tizanidine; because both agents appear to be equally effective, neither agent is preferred over the other for C.B.

Although fatigue is a common problem when caring for infants, C.B. also may be experiencing fatigue related to her MS. She would likely benefit from nonpharmacologic therapy such as avoiding sleep deprivation to the extent possible and concentrating her infant care during the morning hours, enlisting more assistance in the afternoon and evening. She should also be assessed for any symptoms of depression.[44]

CASE 57-2

Question 1: N.R. is a 47-year-old female who was diagnosed with relapsing-remitting MS 5 years ago. She has been taking interferon β-1b 250 μg subcutaneously every other day since diagnosis. For the first 4 years, she did very well with only one relapse. However, in the past year, she has sustained two relapses, and she feels that her treatment is not working as well as it did in the past. Her neurologist sends a blood specimen for neutralizing antibody assay with a result of 160 neutralizing units/mL (reported as high by the laboratory).

How might this result assist in the recommendation of future therapy for N.R.?

Neutralizing antibodies develop in many patients given therapy for MS, including alemtuzumab, β-interferons, natalizumab, ocrelizumab, and ofatumumab. Neutralizing antibodies are seen in up to 44% of patients given interferon-β.[60,65] Fewer patients given interferon β-1a intramuscularly once weekly develop them than those given interferon β-1a subcutaneously three times weekly or interferon β-1b subcutaneously every other day.[65] For patients with persistently high antibody titers, their relapse rates are also higher.[111] With time, neutralizing antibodies often disappear.[65]

Despite these observations, the indications for neutralizing antibody testing and the interpretation of test results are areas of

ongoing controversy. The Therapeutics and Technology Assessment Subcommittee of the American Academy of Neurology has issued the following statements regarding neutralizing antibodies to interferon-β: (a) treatment with interferon-β is associated with the production of neutralizing antibodies; (b) it is probable that neutralizing antibodies, especially in persistently high titers, are associated with a reduction in the radiographic and clinical effectiveness of treatment; (c) it is probable that the rate of neutralizing antibody production is less with interferon β-1a compared with interferon β-1b treatment; (d) it is probable that the seroprevalence of neutralizing antibodies is affected by one or more of the following: formulation, dose, route of administration, or frequency of administration of interferon-β; and (e) there is insufficient information on the utilization of neutralizing antibody testing to provide specific recommendations regarding the indications for testing or interpretation of antibody titer results.[164]

A panel of MS and neutralizing antibody experts was convened in 2009 to develop practical recommendations. Some of their findings are as follows: (a) persistently high titers might provide sufficient guidance to suggest stopping therapy in a patient; however, with low or intermediate titers, additional information might be needed to make a decision regarding therapy continuation; (b) different interferon-β products are associated with different rates of antibody formation; chemical formulation, route of administration, and frequency of dosing appear to have an effect; and different formulations of the same molecule may result in different immunogenicity; and (c) to minimize assay variability, antibody measurements should be done in laboratories that have fulfilled the criteria for validation of neutralizing antibody assays, and interferon β-1a should be used in the assays to standardize the assays.[165] Thus, there is continued discussion about the appropriate use of neutralizing antibody assays for β-interferons.

Antibodies also form to therapies for MS other than the β-interferons. Up to 95% of patients treated with glatiramer acetate have antibodies, but they do not appear to change the efficacy of glatiramer acetate.[166] Antibodies may develop to natalizumab and

may affect treatment efficacy or increase the likelihood of natalizumab infusion reactions. Many patients who express antibodies to natalizumab do so within the first 6 months of treatment, but these antibodies often disappear with continued treatment. Antibodies to natalizumab are more likely to persist if they develop more than 6 months after treatment initiation. High antibody titers are associated with increased rates of relapse and, generally, therapy should be changed.[167] Neutralizing antibodies have been detected with alemtuzumab, but they do not appear to affect efficacy.[141] It is not known if the presence of neutralizing antibodies alters the efficacy of ocrelizumab, and ofatumumab.

N.R. has a high titer of neutralizing antibodies, and they appear to be associated with a decline in efficacy of her interferon β-1b. Therefore, it is appropriate to change therapy at this time. Because of the potential for cross-reactivity of the neutralizing antibodies to other β-interferons, a change to another β-interferon product would not be expected to provide benefit.

Case 57-2, Question 2: N.R.'s interferon β-1b therapy was discontinued, and she was started on teriflunomide 14 mg PO daily. What monitoring will be required while taking this medicine?

Elevated alanine aminotransferase (ALT), alopecia, and diarrhea were seen in 10% to 20% of patients in clinical trials and more commonly in patients treated with teriflunomide than with placebo.[161] White blood cell counts decrease by about 15% and platelets by about 10% during the first 6 weeks of teriflunomide treatment and remain low throughout the treatment. A complete blood count (CBC) is recommended at baseline.[161] Because of the immunosuppression seen, patients should be monitored for infection, and patients should not receive live virus vaccines while under the effects of teriflunomide.[161] Modest increases in blood pressure were also observed. Other required monitoring includes baseline liver enzymes and bilirubin, blood pressure, and screening for latent tuberculosis infection. The monitoring of ALT should occur monthly for the first 6

months of therapy and periodically thereafter.[161] Teriflunomide rarely causes the serious adverse effects of peripheral neuropathy, acute renal failure, hyperkalemia, and bone marrow suppression.[85] Serious adverse effects are not reported with teriflunomide, but those seen with the parent drug leflunomide are Stevens–Johnson syndrome, interstitial lung disease, and hepatotoxicity.[162] Teriflunomide has a very long half-life of ~18 days.[162] Because of this, it can take up to 3 months to achieve steady-state serum concentrations and a proportionally long time to eliminate the medicine (8–24 months). In situations requiring rapid elimination of teriflunomide (eg, serious adverse effects, desired pregnancy), accelerated elimination procedures are recommended. The recommended accelerated elimination procedures are administration of cholestyramine 8 g every 8 hours for 11 days or administration of activated charcoal powder 50 g every 12 hours for 11 days. Verification of elimination should be undertaken by two teriflunomide serum concentrations of <0.02 µg/mL taken 2 weeks apart.[162]

Prior to N.R. starting teriflunomide, her immunization status should be carefully checked, and she should be screened for tuberculosis. If necessary, her immunizations should be updated, and any infectious diseases should be completely treated before starting therapy. She should have a baseline CBC, liver enzymes, bilirubin, and blood pressure. Monthly for the first 6 months, she should have blood drawn for ALT. This would also be an opportune time to check blood pressure and screen for signs of infection.

Case 57-2, Question 3: N.R. successfully began teriflunomide and continued without adverse effects for 1 year. At her annual MRI visit, however, five new lesions were seen in her brain. She continued for another 6 months and had a follow-up MRI with three additional lesions detected. In discussion with her neurologist, she decided to change therapy. Alemtuzumab, cladribine, natalizumab, ocrelizumab, and ofatumumab are considered as therapy alternatives for N.R. How should N.R. be counseled regarding the potential adverse effects and monitoring for these agents?

Recently, there has been interest in defining highly active MS and developing treatment approaches. One definition that has been

advanced is relapsing-remitting MS that meets one of the following criteria: (a) EDSS score of 4 at 5 years after disease onset, (b) multiple relapses (two or more) with incomplete recovery in the current year, (c) more than two brain MRI studies demonstrating new lesions or increases in the size of the lesions despite treatment, and (d) no response to treatment with one or more disease-modifying therapies for at least 1 year.[168] Individuals with highly active MS are usually considered for induction therapy protocols with alemtuzumab, cladribine, fingolimod, natalizumab, ocrelizumab, or ofatumumab.[168–170] There is some evidence that treatment with these medicines is more beneficial if begun early in the disease course.[171–175] Autologous hematopoietic stem cell transplantation is also a consideration.[168,175]

Cladribine has significant adverse effects associated with its use. Because of its mechanism of action, lymphopenia always occurs. Additionally, neutropenia, anemia, and thrombocytopenia occur.[70] Infections, particularly herpes zoster, pyelonephritis, and fungal infections, are also a common occurrence with cladribine treatment.[70] If patients have lymphocyte counts <200 cells/μL, they require anti-herpes prophylaxis.[70] Eleven percent of patients treated with cladribine develop hypersensitivity reactions.[70] Other common adverse effects include headache and nausea. Less common, but severe concerns include development of malignancies, PML, cardiac failure, and heptatoxicity.[70] A thorough evaluation of vaccination needs is recommended prior to beginning treatment with cladribine.[70] There are several drug–drug interactions with cladribine; however, many can be managed by holding the interacting medication for several days around the cladribine dose.[70] Cladribine has a unique dosing regimen with a maximum of two courses divided into two 4- to 5-day cycles given a year apart with significant monitoring associated with each course (**Table 57-8**).[168]

Table 57-8
Monitoring Required for Cladribine Use

Baseline and Before Each Course

▪ Pregnancy test, in females ▪ Complete blood count with differential ▪ Human immunodeficiency virus screening ▪ Tuberculosis screening ▪ Hepatitis B and C ▪ Liver function tests
Baseline
▪ Varicella zoster immunity evaluation and vaccination, if needed ▪ MRI within 3 months
Ongoing
▪ Standard cancer screenings ▪ Complete blood count with differential 2 and 6 months after start of treatment in each treatment course, then periodically

Source: Mavenclad (cladribine). Package insert. EMD Serono; 2019.

Ocrelizumab has been associated with infections, particularly respiratory tract and herpes infections. Infusion reactions may include itching, rash, redness, bronchospasms, dyspnea, pharyngeal or laryngeal edema, hypotension, pyrexia, headache, fatigue, nausea, and tachycardia.[156] To prevent infusion reactions, premedication is recommended with methylprednisolone 100 mg intravenously, an antihistamine, and an antipyretic 30 minutes before the infusion is also recommended.[156] The patient should be monitored for at least an hour following the end of the infusion, although infusion reactions can occur up to 24 hours later.[156] Even with premedication, infusion reactions were seen in 34% to 40% of patients.[156] As with other B-cell depleting therapies, the patient should receive any vaccinations needed prior to start of therapy, and live-attenuated vaccines should not be administered during treatment.[156] It is important to observe all monitoring recommendations during ocrelizumab treatment (**Table 57-9**).

Table 57-9
Recommended Monitoring for Use of Alemtuzumab, Ocrelizumab, and Ofatumumab

Test	Alemtuzumab				Ocrelizumab		Ofatumumab
	Baseline	Monthly for 48 Months After Last Dose	Every 3 Months for 48 Months After Last Dose	Yearly	Baseline	Before Each Infusion	Baseline

Sources: Ocrevus (ocrelizumab). Package insert. Genentech, Inc.; 2020; Lemtrada (alemtuzumab). Package insert. Genzyme Corporation; 2020; Kesimpta (ofatumumab) Package insert. Novartis Pharmaceuticals Corporation; 2020.

Ofatumumab commonly causes infections.[163] Ofatumumab is self-injected subcutaneously and can cause injection reactions such as fever, headache, myalgia, chills, fatigue, erythema, swelling, itching, and pain at the injection site in 11% to 21% of patients with the first injection. The number of patients experiencing injection reactions decreased with further injections.[163] Decreases in immunoglobulin levels were seen in clinical trials, and a baseline should be established before treatment begins (**Table 57-9**).[163] As with other B-cell depleting therapies, the patient should receive any vaccinations needed prior to start of therapy and live-attenuated vaccines should not be administered during treatment.[163]

Several serious adverse effects, infusion reactions, autoimmune conditions, and malignancies associated with alemtuzumab use have caused the FDA to require a limited distribution program for this agent. Infusion reactions associated with alemtuzumab are triggered by cytokine release, may include rash, fever, headache, itching, nausea, and chills, and occur in about 90% of patients; serious reactions occurred in 3% of patients.[51,162] Patients should be

monitored for 2 hours after each infusion, but reactions may occur after that period.[162] Premedication should consist of methylprednisolone 1000 mg infused immediately before the first infusion and for the first 3 days of each treatment course. Antihistamines and acetaminophen may also be helpful premedications.[162] Autoimmune diseases have been associated with alemtuzumab therapy and may include thyroid disorders (34%), immune thrombocytopenia (2%), and antiglomerular basement membrane disease (0.3%).[51,142,162] Thyroid disorders have been seen up to 60 months after the initial treatment with alemtuzumab.[142] Of thyroid dysfunction seen, 73% is hyperthyroidism and 14% is hypothyroidism.[176] Patients receiving alemtuzumab had higher rates of some malignancies, including thyroid cancer and melanoma at a rate of 0.3% each.[142] Infections were more common in patients treated with alemtuzumab than those treated with interferon-β, including urinary tract infections (17%), herpes virus infections (16%), respiratory infections (16%), and fungal infections (12%).[51,142] Infections were more common in the first year of treatment (58.7%), then declined until year 6 (38.1%).[177] The herpes virus infections are most common in the month following the infusion and can be significantly reduced by prophylaxis.[51] The recommendation is that patients receive antiviral prophylaxis for herpetic viral infections starting on the first day of each treatment course and continuing for a minimum of 2 months following treatment or until the $CD4^+$ lymphocyte count is ≥200 cells/μL, whichever occurs later.[162] The dosing of alemtuzumab is unique for MS medicines in that it is a 12-mg/day infusion for 5 days and then an additional 12 mg/day infusion for 3 days 12 months after the first treatment course.[162] No vaccines should be administered during treatment and all should be completed at least 6 weeks prior to treatment, including varicella zoster virus vaccine, if patients have not been vaccinated and do not have a history of infection.[162] Monitoring recommendations can be found in **Table 57-9**.

Adverse effects of natalizumab include fatigue, liver dysfunction, infections, hypersensitivity reactions, and infusion-related reactions.[178] Hypersensitivity reactions are IgE-mediated and occur

within 2 hours of the start of the infusion. Patients who exhibit HLA-DRB1*13 or HLA-DRB*14 are more likely to have hypersensitivity reactions.[179] Genotyping may be helpful to identify these patients prior to natalizumab prescribing. Symptoms include urticaria, dyspnea, and vital sign changes. If these symptoms occur, the infusion should be discontinued.[178] Hypersensitivity reactions should be distinguished from infusion-related reactions. These latter reactions are nonallergic and include symptoms of headache, dizziness, fatigue, nausea, sweats, and rigors. If this type of reaction occurs, there is no need to discontinue therapy; the patient can be pretreated with histamine type 1 and 2 receptor antagonists and acetaminophen.[178]

As previously mentioned, PML is associated with natalizumab therapy. It appears that PML risk is proportional to the duration of natalizumab exposure; one case is reported per 1000 patients in those who have received 24 or more infusions.[154] Overall, reporting appears to occur at a rate of one or two per month.[154] In a 5-year observational cohort study, 0.7% of patients given natalizumab developed PML, two of whom died (4.5% fatality rate).[180] This may be because of the heightened sensitivity to clinical changes that may suggest PML and aggressive immune reconstitution with either plasma exchange or immunoabsorption if PML is diagnosed. However, this immune reconstitution can lead to immune reconstitution inflammatory syndrome (IRIS), which is itself life-threatening. IRIS usually presents as an acute worsening of MS symptoms and is treated with high-dose corticosteroids.[180] Several groups have developed recommendations for natalizumab use to reduce the risk of PML (**Table 57-10**).[153,181]

Table 57-10
Recommendations for Use of Natalizumab

Patients Who Should Not Receive Natalizumab
Immunocompromised
Active viral hepatitis
Active malignancy that requires treatment
Inability to get MRI

Have or have had progressive multifocal leukoencephalopathy
Recommendations for Use
Monotherapy with natalizumab only After failure of interferon or glatiramer acetate Therapy-free interval of 14 days after interferon or glatiramer acetate, 3 months after azathioprine, or 6 months after mitoxantrone
Baseline Testing
Clinical neurologic examination Human immunodeficiency virus testing Complete blood count Liver function tests MRI with IV contrast Anti-JC virus antibody testing
Monitoring
Neurologic examination at 3 months, 6 months, and then yearly MRI with IV contrast at 6 months and then yearly Periodic anti-JC virus antibody testing

IV, intravenous; MRI, magnetic resonance imaging.

Sources: Bartsch T, Rempe T, Leypoldt F, et al. The spectrum of progressive multifocal leukoencephalopathy: a practical approach. *Eur J Neurol*. 2019;26:566–e41; Goodin DS, Arnason BG, Coyle PK, Frohman EM, Paty DW; Therapeutics and Technology Assessment Subcommittee of the American Academy of Neurology. The use of mitoxantrone (Novantrone) for the treatment of multiple sclerosis: report of the Therapeutics and Technology Assessment Subcommittee of the American Academy of Neurology. *Neurology*. 2003;61:1332–1338.

Although approved for treatment of MS, mitoxantrone is no longer commonly used because of significant adverse effects, including nausea, menstrual abnormalities, alopecia, upper respiratory and urinary tract infections, neutropenia, and a temporary change to blue color in the urine and sclera.[76] Dose-related cardiotoxicity occurs with mitoxantrone use, requiring an estimation of left ventricular ejection fraction before each dose.[182] Cardiotoxicity limits the lifetime dose of mitoxantrone to 140 mg/m^2 or ~3 years of therapy. The most common cardiotoxic effects are cardiomyopathy, decreased left ventricular ejection fraction, and irreversible congestive heart failure.[182] Leukemia also occurs with mitoxantrone therapy, usually during the first few years and it may be dose-related.[182]

There is no clear best choice of therapy for N.R. Careful discussion of the potential risks and benefits of each medication should be discussed with her so that her preferences are considered. All of these therapies carry substantial adverse effects about which she will need to be informed. Additionally, she will need to enroll in the restricted distribution systems for the chosen medicine. Another area that requires consideration is that she may be at higher risk for PML or other opportunistic infections when beginning one of these medicines after taking teriflunomide. Conversely, being completely without medicine allows for return or possible "rebound" of disease activity. Possible strategies include undergoing accelerated elimination procedures for the teriflunomide and then (a) allowing for a washout period during which the patient receives no treatment, (b) providing a monthly regimen of methylprednisolone while allowing for a washout period, or (c) switching directly to another therapy without a washout period. It is not known which of these options is best for a patient.

CASE 57-2, QUESTION 4: N.R. experiences another relapse while she is considering which therapy to begin. One month after completing corticosteroid treatment for this relapse, she returns to the neurology clinic for a follow-up appointment. N.R. explains that she has been experiencing episodes of uncontrollable laughing. When these episodes first began, she thought they might be an adverse effect of the corticosteroid treatment for her relapse. However, 1 month after stopping corticosteroid treatment, she is still having these episodes. She states that the episodes are very embarrassing, often occurring at inappropriate times such as in movie theaters, at parent–teacher conferences, and in grocery stores. She is diagnosed with pseudobulbar affect. What treatment is available for pseudobulbar affect, and how should N.R. be counseled regarding this treatment?

Dextromethorphan with quinidine is effective for reducing the rate of pseudobulbar affect episodes and is FDA-approved for this indication. It is dosed one capsule (dextromethorphan 20 mg/quinidine 10 mg) orally twice daily.[183] Adverse effects related to the dextromethorphan component may include dizziness and the possibility of serotonin syndrome. Adverse effects associated with

quinidine are an immune-mediated thrombocytopenia, lupus-like syndrome, hepatotoxicity, dose-dependent QTc interval prolongation, and anticholinergic effects.[183]

There are several drug interactions associated with dextromethorphan–quinidine.[183] It is contraindicated with monoamine oxidase inhibitors, requiring a 14-day washout before starting therapy. Similarly, caution should be exercised when this therapy is used concomitantly with selective serotonin reuptake inhibitors and tricyclic antidepressants. It is contraindicated with drugs that prolong the QTc interval and are metabolized by CYP 2D6. Dextromethorphan–quinidine should be used with caution with drugs that inhibit CYP 3A4. Because quinidine inhibits CYP 2D6, dose adjustments for CYP 2D6 substrates are necessary. Quinidine also inhibits P-glycoprotein, requiring caution and perhaps dose adjustments when this treatment is used in combination with digoxin.

Headache

Steven J. Crosby

CORE PRINCIPLES		CHAPTER CASES
1	Migraine, tension-type, and cluster headache are classified as primary headache disorders. Subtle differences in symptomatology and the presence of auxiliary symptoms assist in defining the headache type.	**Case 58-1 (Questions 1, 2, 3, 6)** **Case 58-2 (Questions 1, 3)** **Case 58-4 (Question 1)**
2	Virtually all patients who suffer from migraine, tension-type, and cluster headaches are candidates to receive abortive (or symptomatic) medications during an acute attack. Prophylactic treatment may be considered for all primary headache types and is driven by various factors, including headache frequency, the level of disability imparted by the headache, and response to acute treatment modalities.	**Case 58-1 (Questions 4, 7–12)** **Case 58-2 (Questions 2, 4, 5)** **Case 58-4 (Questions 2, 3)** **Case 58-5 (Questions 1, 2)**

3	Triptans are the drugs of choice as migraine-specific treatments for acute episodes. Triptans are effective in managing associated symptoms of migraine (eg, nausea, photo- and phonophobia). Differences within the class are observed on the basis of pharmacokinetics.	**Case 58-1 (Questions 5, 7, 8)** **Case 58-2 (Question 4)**
4	Evidence supports the use of propranolol, amitriptyline, or topiramate as first-line agents for migraine prophylaxis. Calcitonin gene-related peptide receptor antagonists represent alternatives for treatment failure or intolerance. The decision to initiate prophylaxis takes into account headache frequency, the impact of attacks on patient functioning, and response to acute treatments. Medical history and adverse effect profile are relevant considerations for specific drug selection.	**Case 58-1 (Question 12)** **Case 58-2 (Questions 5, 6)**
5	Overuse of symptomatic or abortive agents (including triptans and over-the-counter, combination, and opioid analgesics) can increase the intensity and chronicity of all headache types. To prevent medication overuse headache, use of these agents should be limited to <10 days/month.	**Case 58-3 (Question 1)**
6	Cluster headaches are severely painful and short-duration attacks that tend to	**Case 58-4 (Questions 1–3)**

	occur nightly during susceptible periods and then enter remission for a period of months or years. Treatments of choice for abortive treatment must be fast-acting and include subcutaneous sumatriptan, intranasal zolmitriptan, and oxygen inhalation.	
7	Tension-type headaches (previously known as tension or muscle contraction headaches) usually cause mild-to-moderate discomfort. Conventional analgesics are often appropriate for acute management. Some patients with tension-type headache may require prophylactic treatment, for which amitriptyline, mirtazapine, and venlafaxine have demonstrated efficacy.	**Case 58-5 (Questions 1, 2)**

INTRODUCTION

Epidemiology

The prevalence of migraine in the United States approximates 15%.[1] There is noted variability in the data relative to parameters of sex and age, with a higher incidence observed in females, and a decline observed with advancing age.[1] Such age- and gender-associated prevalence has been further substantiated in surveillance reviews.[2] Across ambulatory care settings, migraine accounts for 0.5% of all encounters, with a majority occurring in primary care settings, whereas emergency department (ED) visits ~3%,[1,3] being further stratified within the top 10 causes for ED encounters in the United States.[2]

Classification

There is inherent difficulty in evaluating and classifying headache, because this symptom may be attributed to physiologic, psychological, or pathologic process or may be an adverse outcome associated with medications. The completion of a comprehensive assessment of the patient is critical for adequate management. Broadly categorized, headache is defined as primary or secondary, with the latter typically being attributable to an organic cause. Primary headache is inclusive of migraine, tension headache, and trigeminal cephalalgias, of which cluster headache would be one category. Further, headache associated with physical activity, exposure to exogenous stimuli, or those evolving during the sleep cycle would be categorized as primary.[4] Secondary headache may be attributable to, but not limited to, traumatic injury, vascular or nonvascular cranial pathology, tumor formation (neurofibroma), or an infectious process.[4]

The appropriate classification ultimately speaks to the larger issue of optimal management, via either medical procedures or the initiation of medication. Secondary headache is associated with a causative component.[4] Targeting that cause becomes a principle intervention strategy.

PRIMARY HEADACHE DISORDERS

Migraine

The timeline for the evolution of migraine can often be expressed in terms of minutes. The clinical assessment process for differentiating headache type is dependent upon recognizing general characteristics of migraine and further distinguishing such characteristics from other primary headache forms. An assessment of location can be useful but is not a prime differentiator between headache types because migraine location can be unilateral or bilateral in nature. Patient assessment should include an evaluation of both pain intensity and pain quality because migraines are commonly described as moderate-to-severe pulsating pain.[4]

Migraine duration typically ranges from 4 to 72 hours and may be accompanied by auditory (phonophobia) and light (photophobia) sensitivity, as well as nausea and vomiting.[4,5] These auxiliary symptoms are mediated via the hypothalamus and the chemoreceptor trigger zone (CTZ), indicating diffuse neuroanatomic involvement. The aforementioned features have demonstrated reliable predictive value in migraine diagnosis, as defined by the POUND mnemonic (pulsating, 4- to 72-hour duration, unilateral nature, nausea or vomiting, disabling effect).[6] The presence of four out of the five criteria indicates high probability of migraine.[6]

Migraine may be preceded by a constellation of optical or sensory features, defined as an aura. The presence or absence of an aura highlights an important differentiator in migraine diagnosis. International Classification of Headache Disorders criteria indicate a disparity in the number of episodes consistent with a diagnosis of migraine without aura (eg, minimum of five episodes) versus migraine with aura (eg, minimum of two episodes).[4] This criterion is not the only parameter considered, because additional criteria pertaining to headache characteristics also need to be met for an appropriate migraine diagnosis. Auras most often affect vision, with either positive (eg, visual feature) or negative (eg, localized blindness) character.[4] Sensory effects can be characterized similarly as positive (eg, pins and needles description) or negative (eg, loss of sensation or numbness)[4] (**Table 58-1**). Aura character that extends beyond the visual and sensory, such as motor or speech irregularity, is linked more toward specialized migraine diagnoses.[4] Patients with suspected migraine should be advised to document aura timing and description because this information can be valuable for accurate diagnosis.

Table 58-1

Comparative Diagnostic Criteria for Migraine and Migraine With Aura

Criterion	Migraine	Migraine With Aura

Criterion	Migraine	Migraine With Aura
Occurrence	Minimum of five episodes	Minimum of two episodes
Duration	4–72 hours	4–72 hours
GI symptoms	Yes	Yes
Light- and/or auditory-sensitivity	Yes	Yes
Aura presence	No	Yes
Aura symptoms	None	Visual and/or sensory effects occur more frequently. Disturbances in motor function and/or speech may also occur. Motor and speech disturbance are less frequent.

Source: Headache Classification Committee of the International Headache Society (IHS). The International Classification of Headache Disorders, 3rd edition. *Cephalalgia*. 2018;38(1):1–211. © 2018 SAGE Publications. Reprinted by permission of SAGE Publications, Inc.

Table 58-1 provides a comparison between migraine and migraine with aura diagnoses.

The location of migraine pain may be widespread because of the branching of the trigeminal nerve, which facilitates sensory effects across facial regions. Anatomically, the trigeminal nerve features branches of V1, V2, and V3.[7] Branch V1 innervates the scalp, orbital region, and meninges; V2 is directed to the top of the jaw and sinus region; and V3 innervates lower mandibular regions.[7] Additionally, patients may report pain referral to the suboccipital region because of the proximity of occipital nerves and the spinal nucleus.[7]

Cluster headache

Cluster headache is characterized within the domain of primary headache disorders. Cluster headache is primarily unilateral involving orbital and/or temporal pain, which can persist for up to 3 hours.[4] Independent of duration, such episodes may occur multiple times during the day.[4] Associated symptoms that occur with high

prevalence during cluster headache include lacrimation, rhinorrhea, miosis, ptosis, diaphoresis, and flushing.[4] Preferential incidence of cluster headache occurs in males, but there is similarity to migraine on the basis of age prevalence.

Tension-type headache

Tension-type headache is of bilateral character and, by comparison to migraine, is often associated with less intense pain without a pulsating quality. An individual's subjective description of pain quality and intensity can be useful in differentiation. Patients may use such terminology as "tightening" to characterize symptoms. The *combination* of symptoms of photophobia, phonophobia, and nausea/vomiting is not considered to be consistent with the diagnosis of tension-type headache; however, the *individual* symptoms of photo- or phonophobia may accompany tension-type headache.[4]

SECONDARY HEADACHE

Causation is the key principle underlying secondary headache. Such attributable causes include head or neck trauma, cervical vascular dysfunction, nonvascular cranial dysfunction, infection, psychiatric pathology, or substance withdrawal effects.[4] Causation becomes a critically important principle to consider in patient assessment, particularly when headache onset deviates substantially from existing prevalence and epidemiologic data.

Acute headaches

Acute headaches may be linked to subarachnoid hemorrhage, stroke, meningitis, or intracranial mass (eg, neurofibroma, abscess). It is within this clinical context that diagnostic measures of neuroimaging and lumbar puncture are more commonly implemented. Commonalities of headaches associated with such pathology are of severe quality and rapid evolution, perhaps described as the "worst headache" experienced. An increase in intracranial pressure is of particular importance, and recognition of

factors that can affect intracranial pressure becomes critical in patient assessment.

Subacute headaches

Subacute headaches may be a sign of increased intracranial pressure, intracranial mass lesion, temporal arteritis, sinusitis, or trigeminal neuralgia. Trigeminal neuralgia usually occurs after the age of 40 and is more common in females than in males. The pain usually occurs along the second or third divisions of the trigeminal (facial) nerve and lasts only moments. Trigeminal neuralgia is characterized by sudden, intense pain that recurs paroxysmally, often in response to triggers such as talking, chewing, or shaving.

The evaluation of headache pathology should incorporate the consideration of reported prevalence data, patient age, the presence of triggers or aggravating factors, the contribution of past medical history to headache origin, the patient's description and characterization of symptoms and frequency, and any record of self-care interventions employed to manage headache. Evaluating the impact of headache on daily activity and function is a similarly important consideration. A diagnosis may be confirmed on the basis of this information without the need for further laboratory or procedural measures. If objective or subjective information becomes suggestive of a clinical anomaly (eg, late-age onset of headache, suspected structural anomalies, or neural tissue pathology), a more comprehensive evaluation, inclusive of additional diagnostic measures (eg, imaging, lumbar puncture), is indicated. Imaging will be valuable in the identification of neurofibromas and potential changes in white matter.

Pathologic Basis

The pathologic picture of headache requires an understanding of vascular physiology and the functions of the trigeminovascular circuit and neuropeptides. Headache involves both peripheral and central pain processing, afferent neuronal excitability, and pain sensitivity of

cerebral arteries and venous sinuses.[4,8] The pathology has often been described within the context of interactions between vascular and neurologic systems.[5,9] Muscular tenderness similarly contributes to headache pathology.[8,10] Such an effect is more closely linked with tension headache.

The interplay between vascular and neurologic function is of considerable importance. Afferent and efferent fibers of the trigeminovascular circuitry, vasoactive neuropeptides stored within this system, and serotonin (5-HT) maintain significant pathologic importance.[5,11,12] Neuropeptides, such as substance P, neurokinin A, nitric oxide, calcitonin gene-related peptide (CGRP), and adenylate cyclase-activating peptide, are promoters of neuroinflammation and vessel dilation.[5,12] The vasodilatory potential of CGRP has been widely established, with evidence of increased synthesis during episodes of inflammation.[13] It is a process of continually promoting vasodilation. Evidence further suggests an elevation in pro-inflammatory C-reactive protein in migraine sufferers compared to controls.[14] Therapeutic interventions have focused on modulating the effects of 5-HT with recent efforts directed toward the modulation of neuropeptide function.

Drug Therapy

The primary goal of therapy is the resolution of headache symptoms, most prominently pain, and attenuating disability associated with the headache. Nonpharmacologic recommendations should similarly be paired with therapeutic options. Pharmacologic treatment options can be divided into abortive and prophylactic, the former resolving acute episodes and the latter being administered chronically to reduce the incidence of recurrent headaches. Abortive treatment may sufficiently manage tension-type headache, often negating the need for prophylactic treatment; however, this may be considered when acute treatment is ineffective, overused, or when the headache is chronic or occurring in frequent episodes. Conversely, patients with migraine and cluster headache, while requiring abortive

treatment, may commonly also require long-term prophylactic treatment.

Success in managing acute episodes can often be achieved with the use of conventional analgesics or headache-specific medications (eg, triptans, CGRP antagonists). Medication selection should be based on the patient's prior treatment experience and the level of disability imparted by the headache episode. With regard to prophylactic therapy, evidence supports the use of CGRP monoclonal antibodies, select antidepressants, anticonvulsants, and antihypertensives. The selection of such agents should be considered within the context of adverse effect profiles and the potential for utility in managing other medical conditions (eg, prescribing a β-antagonist for migraine prophylaxis in a patient with a history of hypertension).

MIGRAINE HEADACHE

Migraine is characterized by pain of a throbbing quality with moderate-to-severe intensity and the presence of associated symptoms, including nausea, vomiting, light, and/or auditory sensitivity.[4,5] Migraine can be unilateral or bilateral and can be further classified on the presence of an aura.[4] The occurrence of an aura has diagnostic relevance based on the number of episodes and can encompass a range of sensory disturbances, not solely limited to visual field effects.[4]

Pathophysiology

Vascular constriction was a prior central focus of migraine pathology, resulting in hypoperfusion and being resolved through compensatory vasodilation.[5,15] Such alterations in blood flow have been observed in neuroimaging of migraine patients.[5,16–18] There are further alterations in neuronal depolarization, termed cortical spreading depression.[5,19,20] There has been further demonstration of causality

between cortical spreading depression and the activation of trigeminovascular circuitry.[5,21] The trigeminovascular system consists of afferent fibers with a foundation in trigeminal ganglia, projecting peripherally to intracranial blood vessels and venous sinuses and to extracranial tissues.[5,21] Activation of the trigeminovascular system facilitates the release of vasodilatory-promoting neuropeptides (eg, substance P, neurokinin A, CGRP, nitric oxide), and subsequent release results in vessel dilation and inflammation.[5,12,22,23] The elevation of neuropeptides has become an increasingly important component of the pathologic process. There are noted elevations in CGRP and pituitary adenylate cyclase–activating polypeptide.[24,25] The presence of CGRP in the trigeminal system is significant, and further activity at the level of the trigeminal nucleus caudalis supports the propagation of pain impulses in various neuroanatomical regions.[26]

Migraine pathology is multifaceted and neuroanatomically diffuse, involving the brainstem trigeminal nuclei, trigeminovascular afferents, thalamus, hypothalamus, CTZ, and cortical regions. Therapeutic strategies target the dysfunction in these regions, the mediation of associated symptomatology, and the modulation of neuropeptides and serotonergic neurotransmission.

GENETICS

The genetic basis of migraine is most effectively understood within the context of familial hemiplegic migraine. This subtype has been further categorized into multiple mutation-induced forms with associated genes *CACNA1A*, *ATP1A2*, *SLC1A3*, *SLC4A4*, and *SCN1A*.[27,28]

Such genes encode α_1-subunits (*CACNA1A*, *SCN1A*) and α_2-subunits (*ATP1A2*) or are linked with glutamate-associated (SLC1A3) and sodium bicarbonate–associated (SLC4A4) transporters.[5,29]

A further genetic linkage with migraine pathology has been identified in *TRESK*, *TREK1*, and *TREK2*.[30] As the co-expression of these potassium channels is observed in trigeminovascular circuitry,

mutations at this level contribute to altered neuronal function.[30] Advances in the understanding of the genetic bases for pathology maintain importance, as such developments impart promise for novel interventional strategies.

Assessment Tools

Various patient assessment instruments used to evaluate headache impact include the Headache Impact Test (HIT-6), Migraine Disability Assessment (MIDAS), and the Migraine-Specific Quality of Life Questionnaire (MSQ). The HIT-6 uses a Likert scale and evaluates pain, social and cognitive function, and psychological impact.[31,32] A higher score on this assessment confers a greater headache impact. Rendas-Baum et al[32] confirmed validation of this instrument in the context of chronic migraine. The MIDAS is a self-administered, seven-item questionnaire, assessing headache-induced absenteeism, activity limitations, and headache frequency and intensity. This instrument has demonstrated reliability and validity.[33–35] The MSQ addresses migraine impact across patient social activity, emotional activity, and the capacity of migraine to prevent activity.[32] With established validity and reliability,[36–38] strong correlations between the MSQ and HIT-6 have been confirmed in the context of chronic migraine.[38]

MIGRAINE WITHOUT AURA

CASE 58-1

Question 1: L.P. is a 27-year-old female presenting to her primary care physician (PCP) with a "severe, throbbing headache." L.P. reports that headaches began 18 months ago, but during the past 3 months, headaches have been occurring with greater frequency, approximating one episode every 2 to 3 weeks. She further describes bilateral headache pain, occurring "without warning," and coinciding symptoms of nausea and vomiting, photophobia, and suboccipital pain. Prior episodes have been self-treated with oral acetaminophen 500 mg (2–4 tablets/ episode as needed) with variable efficacy. Her past medical history is significant for generalized anxiety disorder (GAD),

gastroesophageal reflux disease (GERD), and seasonal allergies. Current medication usage includes levonorgestrel/ethinyl estradiol 0.10/0.02 mg by mouth daily, venlafaxine XR 75 mg by mouth daily for GAD, and omeprazole 20 mg by mouth daily × 2 months for recent-onset GERD symptoms. Social history is negative for tobacco use and illicit substances. L.P. reports occasional consumption of alcohol, stated as "1 to 2 cocktails after work on Fridays." As headaches have occurred with greater frequency, she has missed time at work and this issue has prompted a visit with the PCP. Physical and neurologic examinations are unremarkable.

What subjective and objective information is consistent with a migraine diagnosis, and how do these signs/symptoms differ from tension-type headache?

Symptoms reported by L.P. are consistent with migraine. For L.P., migraine location would not be a differentiating characteristic between migraine and tension-type headache, because tension-type headache is more commonly associated with bilateral character.[39] Pain quality, described as "severe" and "throbbing," is consistent with migraine and precipitates interruptions with daily activity (eg, absenteeism from work) contrasted with tension headache that is associated with sensations of tightness or soreness.[39] Similarly, the occurrence of nausea, vomiting, and photophobia more appropriately aligns with migraine.[4] L.P.'s sex and age would be compatible with prevalence data for migraines.[1]

Case 58-1, Question 2: Which characteristics may be classified as precipitating factors, or "triggers," for migraine pathology? What are possible precipitating factors in L.P.?

Factors involved in precipitating migraine should be routinely assessed for all patients. Assessment should address factors within a patient's medical history, medication usage, social history, and environment. L.P.'s medical history is significant for GAD. Alterations in neurotrophic factors and an increase in anxiety symptoms have been demonstrated in migraine patients.[40] Such evidence imparts value to assess this aspect of L.P.'s medical history. She denies use of tobacco and illicit substances but does report the occasional use of alcohol. Although the consumption of alcohol should be

addressed, the linkage between alcohol consumption and precipitating migraines is less clear.[41,42] The potential provocation of cortical spreading depression, an electrophysiologic factor underlying migraine pathology, in association with alcohol has been suggested.[43] Although not reported by L.P., an evaluation of diet may provide useful information in determining migraine triggers. The evaluation of dietary patterns and quality has yielded disparities, reporting lower-quality dietary intake in migraine patients.[44]

Case 58-1, Question 3: Are further diagnostic and laboratory tests indicated in the case of L.P.?

The most important diagnostic evaluations of patients presenting with headache should be based on a thorough medical history and physical examination. Imaging (eg, computed tomography [CT] scans, magnetic resonance imaging [MRI]) is generally not required in the context of uncomplicated migraine.[45] The report of symptoms by L.P. is consistent with migraine and is sufficient for diagnosis. Her symptoms are not associated with a secondary cause, such as trauma or other injury to the head or neck, and her neurologic examination is unremarkable. Similarly, without reason to suspect subarachnoid hemorrhage or symptoms secondary to meningitis, lumbar puncture would not be indicated. Clinical manifestations that may warrant neurologic imaging to identify artifacts or structural anomalies include coordination deficits, localized neurologic pathology, sensory manifestations, an abnormal neurologic examination, or the presence of atypical headache characteristics.[45] Any change in headache character or headache onset with advanced age warrants consideration for neuroimaging.[6]

Case 58-1, Question 4: What are the goals of therapy for the management of headache in L.P.?

The approach to management and the treatment objectives for L.P. include resolving the acute symptoms of pain, nausea, and

photosensitivity, educating L.P. on both prescription and self-care treatment, addressing the contribution of past medical history and concurrent medication usage to headache episodes, and identifying potential triggers.

Case 58-1, Question 5: What is the most appropriate recommendation with regard to the use of acetaminophen to treat headache episodes in L.P.?

L.P. has confirmed self-treatment of headaches with acetaminophen, and in such instances, it is critical to not only evaluate each patient's potential for self-care but also determine whether self-care treatment options can effectively and safely manage the diagnosis. Reported efficacy of acetaminophen has been mixed. Trial data has provided evidence of oral acetaminophen efficacy, in combination with aspirin and caffeine, in migraine treatment.[46] Doses of 1000 mg have demonstrated efficacy and have provided improvement in associated symptoms.[47,48] However, a study evaluating the parenteral administration of acetaminophen for acute management found no significant difference in efficacy versus placebo.[49,50] Considering L.P.'s report of variable efficacy and increase in headache frequency, she is not an appropriate self-care candidate and continued, routine use of acetaminophen to manage acute episodes is not recommended.

Case 58-1, Question 6: What drug-related problems associated with the precipitation or worsening of migraine should be addressed in L.P.?

Oral contraceptives may either worsen or precipitate migraine attacks in females without a previous history of this problem.[51] Incidence may be related to estrogen dose and/or duration of oral contraceptive use.[52,53] Alternatively, migraine has been implicated as an effect of estrogen withdrawal.[52] Such patients may benefit from use of a continuous combined oral contraceptive product (eg, one with no hormone-free interval), use of low-dose estrogen

supplementation after 21 days of active contraceptives, or the use of a progestin-only oral contraceptive.[51,54,55]

The American Congress of Obstetricians and Gynecologists supports oral contraceptive use in migraine patients but recommends avoidance in patients with tobacco use, in those 35 years and older, and/or in those with the presence of neurologic signs.[56] None of these factors are present in L.P.; therefore, oral contraceptive use may be continued. The implications of oral contraceptive usage and headache should be discussed with L.P. to allow for informed decision-making.

Consultation with L.P. should address whether GAD is being optimally managed. The innervation of trigeminovascular circuitry by neurotransmitters (eg, norepinephrine, 5-HT) linked to affective pathology (eg, anxiety, depression) has been established[57] and is known to coexist with such patients reporting increased headache frequency.[58] It is prudent to address anxiety management with L.P. and to further assess her response to venlafaxine to determine whether dose adjustments or medication changes are warranted.

Case 58-1, Question 7: What strategies and medication recommendations can be used as first-line treatment for L.P.?

Treatment should be aimed at rapidly resolving symptoms and the restoration of the patient's routine activity.[59] Migraines may be managed via a "step" or "stratified" approach.[59,60] With a "step" care model, conventional analgesics are initiated first with the opportunity to progress to using more targeted therapies as necessary.[59,60] A "stratified" care model is based on the character of the migraine and will further incorporate validated assessment measures into the treatment decision.[59,60] The current treatment approach for L.P. has mimicked a "step" care model, using acetaminophen as a first-line medication.

Triptans (5-$HT_{1B/1D}$ receptor agonists)

Triptans, categorized as first (sumatriptan) and second generation (zolmitriptan, naratriptan, rizatriptan, almotriptan, frovatriptan, and eletriptan), are effective and well tolerated in acute migraine management and are considered appropriate for those not responsive to conventional analgesics. Triptans can be compared on the basis of efficacy, onset, and recurrence potential. Naratriptan and frovatriptan demonstrate lower recurrence potential, whereas the remaining agents within the class yield higher efficacy and faster onset.[59] Compared with ergot derivatives, triptans exhibit greater receptor subtype specificity, targeting 5-HT_{1B} and 5-HT_{1D} receptors.[59,61] It is important to note that the specific nature of the effect differs according to receptor subtype. Constriction of the vasculature is mediated via 5-HT_{1B} interaction,[59,61,62] whereas interaction via 5-HT_{1D} antagonizes the release of neuropeptides.[59,62] Evidence supports alterations induced by triptans in the interplay between trigeminal nuclei and higher cortical regions.[63]

Sumatriptan

Sumatriptan is the prototype of the triptan class and is available in several formulations. A systematic review confirmed efficacy relative to placebo across sumatriptan doses and formulations; however, subcutaneous delivery yielded a more robust analgesic response.[64] Migraine intensity and the character of associated symptoms (eg, severity of nausea and vomiting, early-onset nausea) impact formulation selection. For patients who are nauseated and prone to vomit during an acute attack, the subcutaneous and intranasal dosage forms are preferred. Both formulations have a rapid onset of effect. Reduction in headache intensity is reported within 10 minutes after subcutaneous injection and within 15 minutes after administration of the nasal spray.[65] A proof-of-concept trial yielded a significant difference in pain reduction, compared with placebo, for a 3-mg subcutaneous sumatriptan dose. Superiority to placebo was also demonstrated for the resolution of auditory and light sensitivity effects.[66] An advancement in formulation has been realized with the development of a breath-powered intranasal powder, and a more

favorable pharmacokinetic profile with a reduction in T_{max} and an AUC increase relative to the sumatriptan oral and nasal spray formulations has been observed.[67–70] A key finding was the improved management of emergent nausea relative to oral administration.[70]

Adverse Effects

Although sumatriptan is well tolerated, there is some variability in the adverse effect profile across different formulations. Both oral and intranasal sumatriptan formulations are associated with a low incidence of systemic adverse events. Oral administration of sumatriptan has been associated with adverse effects, including dizziness, fatigue, nausea, and vomiting,[71,72] whereas intranasal administration may cause abnormal taste and nasal discomfort.[67,68] Parenteral administration is associated with bruising, redness, and discomfort at the injection site.[73] Because of the risk of vasoconstriction associated with triptan use, special attention is required for patients with cardiovascular disease or risk factors. The provocation of coronary artery spasm secondary to sumatriptan administration has been demonstrated in those with variant angina, an effect likely mediated via the 1B receptor subtype.[74] A baseline electrocardiogram is recommended for patients with potential cardiac risk prior to triptan administration and may be considered for those patients without cardiovascular risk factors experiencing chest tightness following triptan administration.[75]

Drug Interactions

Drug interaction potential associated with sumatriptan centers on the modulation of serotonergic activity, the risk of serotonin syndrome, and the potential for additive vasoconstrictive properties. A 2006 Food and Drug Administration (FDA) advisory further underscored the need for caution and consideration of risk versus benefit with the use of triptans in combination with selective serotonin-reuptake inhibitors (SSRIs) and serotonin/norepinephrine-reuptake inhibitors (SNRIs).[76]

The medication profile for L.P. includes venlafaxine, an SNRI, for the management of GAD; however, this does not exclude the possibility of using triptans to manage her migraines. The clinician should evaluate the entire regimen to ensure optimal management of all indications, and if the addition of a triptan is deemed appropriate, L.P. should be educated on the potential for interaction and the clinical implications of the combination. Because L.P. has attempted treatment with conventional analgesics, she would be a candidate for initiating sumatriptan.

Case 58-1, Question 8: During her annual physical examination, L.P. reports success in managing her migraines with sumatriptan but notes that two doses are often required for resolution of symptoms. She inquires as to whether another triptan would be more effective. How do second-generation triptans compare with sumatriptan? Is an alternative triptan appropriate for L.P.?

Second-generation triptans

Second-generation triptans include almotriptan, eletriptan, frovatriptan, rizatriptan, naratriptan, and zolmitriptan. These agents differ based on the pharmacokinetic profile and the capacity for headache recurrence.[59,77] Among the class, zolmitriptan, rizatriptan, eletriptan, and almotriptan are associated with a faster onset and higher likelihood of recurrence compared with naratriptan and frovatriptan, both of which have a slower onset of action with a lower risk of recurrence.[59,77] Comparisons of 74 randomized trials found that among the triptans, eletriptan was associated with the greatest potential of producing a pain-free state at 2 hours and at 24 hours.[78] Favorable efficacy was further observed for rizatriptan (2 hours) and zolmitriptan (24 hours).[78] Comparisons between rizatriptan and frovatriptan have yielded similar pain-free outcomes at 2 hours and have favored frovatriptan for pain-free status at 4 hours.[79] An assessment of sustained headache relief, using a 24-hour window, yielded the most substantial benefit with zolmitriptan and eletriptan.[80] These agents were also associated with minimal usage of additional "rescue" medication.[80]

Drug Interactions

Striking the balance between theoretic drug interaction risk for triptans and what is observed in clinical practice presents a challenge, especially because it relates to the risk of serotonin syndrome.[76,81,82] For L.P., potential drug interactions exist between triptans and venlafaxine (SNRI) and levonorgestrel/ethinyl estradiol (oral contraceptive). Attributed to metabolism via CYP1A2, a slight increase in frovatriptan AUC has been observed with oral contraceptive administration.[83] Prospective investigations assessing the combination of paroxetine and rizatriptan and fluoxetine and zolmitriptan found no instances of serotonin syndrome.[81] Similarly, there were no significant pharmacokinetic and pharmacodynamic alterations when assessing the combination of fluoxetine and almotriptan.[84] These studies lie in contrast to reports of symptoms of serotonin syndrome with the combination of triptans and SSRIs or SNRIs.[65] The administration of a triptan should not be excluded based on L.P.'s medication profile; however, educating her on the potential for the interaction is warranted.

Increases in rizatriptan and zolmitriptan exposure have been observed secondary to monoamine oxidase (MAO) inhibition.[82] Inhibition of CYP3A4 results in increased eletriptan[82] and almotriptan exposure.[82,85] Frovatriptan is not a substrate for CYP3A4 and represents an alternate treatment option is such instances.[86,87]

L.P. can be considered an appropriate candidate for a triptan. Although associated migraine symptoms are reported, the rapidity of onset for such symptoms (eg, nausea, vomiting) is less clear and should be a point of discussion with the patient. Such information is important for optimal formulation selection. A nonoral formulation may be recommended in the context of early-onset vomiting. Although a loss of efficacy is associated with triptan discontinuation,[88] the timeline for triptan use prior to discontinuation has spanned years.[88] Evidence for replacing one triptan with another is mixed. If treatment with one triptan results in suboptimal efficacy, an alternative triptan may be prescribed.[77] However, evidence

evaluating the impact of such change does not suggest substantial benefit.[89,90]

CASE 58-1, QUESTION 9: L.P. has noted that for some migraine episodes, nausea and vomiting has been severe, and asks about the use of dihydroergotamine (DHE) and antiemetics. What is the role of ergot alkaloids and/or antiemetics in migraine management?

ERGOT ALKALOIDS

Relative to triptans, ergot alkaloids function as receptor agonists with strong affinity at 5-HT_{1A}, 5-HT_{1B}, and 5-HT_{1D}.[91] In addition, these agents express activity at 5-HT_{1F} as well as α-receptors and dopaminergic receptors.[91,92] This pharmacologic profile differs from that of the triptans because the latter exhibit no affinity for dopaminergic or α-receptors.[91] Actions of ergot alkaloids are multifaceted, blocking neuropeptide release, stimulating the ventroposteromedial thalamus, and blocking transmission of afferent signals in the trigeminal circuit.[91] Although ergot alkaloids have demonstrated benefit in managing migraine,[77] the more targeted pharmacologic profile of the triptans has gained preference.

Orally inhaled DHE is a noninvasive delivery system that has demonstrated superiority to placebo across end points of pain relief and freedom from auditory sensitivity, light sensitivity, and nausea.[93,94] Associated adverse effects included product taste and nausea, 6% and 4%, respectively.[93] This delivery system is not commercially available.

Peripheral and cerebrovascular disease, renal and hepatic disease, sepsis, and cardiac disease qualify as contraindications to the use of ergot alkaloids.[91,95] Because of the potential to induce uterine contraction and distribute into breast milk, use is contraindicated during pregnancy and lactation.[91,96] In patients with a history of hypertension, it is important to determine whether blood pressure is appropriately controlled before considering the use of these agents in migraine because of the potential for peripheral arterial constriction.[97] Compared with ergotamine, DHE exerts a

more variable effect on blood pressure.[97] Despite such variability, DHE is not recommended for use in patients with an unstable cardiovascular status.

Adverse effects

Nausea is the most prominent adverse outcome with ergot alkaloids.[97] The effect is dose-related and is linked with 5-HT_2 and 5-HT_3 receptor activation.[59] Intranasal DHE and orally inhaled DHE have been associated with prolonged nasal congestion[59] and altered taste.[93] Parenteral administration has been associated with lightheadedness and leg cramping.[97]

Antiemetics

In most patients, triptans provide effective relief of migraine-associated nausea. Therefore, specific antiemetic therapy usually is not required. However, persistent nausea is more common in patients who use ergotamine for acute migraine therapy. In these patients, and in triptan-treated patients who experience incomplete nausea relief, adjunctive antiemetic therapy should be considered. Demonstrated improvement in emesis has been observed with metoclopramide and granisetron.[98] Comparable efficacy in nausea management has been noted for intravenous (IV) prochlorperazine 10 mg and IV metoclopramide 20 mg.[99] Efficacy of intravenous metoclopramide has been demonstrated at the lower end of the dosing scale (10 mg), but higher doses (20–40 mg) were not associated with improved outcomes.[100]

Case 58-1, Question 10: In addition to triptans and ergot derivatives, what other abortive agents are available for outpatient treatment of acute migraine?

CGRP receptor antagonists

Efficacy and tolerability of ubrogepant (a calcitonin gene-related peptide receptor antagonist [CGRP-RA]) has been evaluated in the ACHIEVE II clinical trial (phase 3, multicenter, randomized, double-

blind, placebo-controlled single attack study to evaluate the efficacy, safety, and tolerability of oral ubrogepant in the acute treatment of migraine). Efficacy in managing migraine pain (achievement of a pain-free state at 2 hours) for ubrogepant, compared to placebo, was confirmed for doses of 50 and 25 mg following oral administration.[101,102] The amelioration of auxiliary migraine symptoms (photo- and phonophobia, nausea) was observed with the 50-mg dose.[101] Superiority to placebo in achieving a pain-free condition at 2 hours has also been demonstrated with a dose of 100 mg.[103] Similar clinical outcomes have been observed for comparisons between rimegepant and placebo.[104–106]

Ubrogepant and rimegepant are alternatives to triptans in the management of acute migraines. There is insufficient evidence to support the complete replacement of triptans by CGRP-RAs for managing acute migraines. However, these agents should be considered for patients experiencing suboptimal triptan response (failed trials of triptans), or intolerable triptan effects. Patients that report experiencing "triptan sensations" (eg, flushing, chest tightness) are viable candidates for CGRP-RAs, if such effects do not resolve. The effect on the vasculature represents a primary advantage in the use of these agents.[106–108]

In comparison with triptans, CGRP-RAs do not exhibit potential for vasoconstrictive effects.[107,108] The lack of vasoconstriction associated with these agents supports the use in patients with cardiovascular and/or cerebrovascular disease. There is similar utility for patients with disease states exacerbated by vasospasm (eg, Raynaud).

The use of CGRP-RAs may also be considered in the context of concerns with serotonergic modulation. Although triptans are not contraindicated for patients maintained on serotonergic agents, concerns regarding augmented serotonergic effects are bypassed with the use of CGRP-RAs.

Adverse outcomes include hepatic enzyme elevations, incidences of upper respiratory tract infection,[109] and nausea.[105]

5-HT_{1F} receptor agonists

Lasmiditan is a 5-HT_{1F} receptor agonist for acute migraine management. With demonstrated selectivity for the 1F receptor subtype, coupled with limited affinity for receptor subtypes targeted by triptans, lasmiditan represents an alternative with limited vasoconstrictive action.[110,111] Doses of 100 and 200 mg have yielded efficacy in acute management relative to placebo.[111]

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS AND COMBINATION ANALGESICS

Many nonsteroidal anti-inflammatory drugs (NSAIDs) and combination analgesics containing caffeine have been shown to be effective for the acute treatment of migraine headache.[112,113] Significant clinical benefit in double-blind, placebo-controlled trials has been shown for aspirin, ibuprofen, naproxen sodium, and combination analgesics containing acetaminophen, aspirin, and caffeine.[113,114]

Case 58-1, Question 11: L.P. reports that her migraines have been successfully managed with naratriptan 2.5 to 5 mg/episode, with most episodes resolving with the lower dose. Naratriptan was selected on the basis of a lower likelihood of recurrence. L.P. has been experiencing a severe migraine for the past few days and has been unsuccessful in treating the episode with naratriptan. She has now sought treatment at a nearby hospital and has been diagnosed with status migrainosus. What is the most appropriate approach to managing status migrainosus in L.P.?

Intractable Migraine

Status migrainosus, or intractable migraine, is characterized by an extended duration of headache, exceeding 72 hours.[4] The typical management strategy usually requires hydration and parenteral therapy with ergot derivatives, sumatriptan, or opioid analgesics.

DIHYDROERGOTAMINE

Dihydroergotamine has demonstrated efficacy in treating intractable migraine by either intermittent or continuous administration.[115]

Adjunctive antiemetics should be administered for nausea.[115,116]

SUMATRIPTAN

Sumatriptan 6 mg subcutaneously is also effective for the treatment of established migraine.[65] If the first injection does not provide relief at 1 hour, a second injection may be administered. Sumatriptan should not be administered within 24 hours of ergot alkaloids because of the potential for prolonged vasospastic reactions.

PROCHLORPERAZINE

Prochlorperazine has established efficacy in managing migraine-related nausea, with intravenous administration being effective during intractable migraine.[115,117] In randomized, controlled trials, prochlorperazine 10 mg IV was more effective than placebo, IV metoclopramide, IV ketorolac, and IV valproate for the treatment of acute migraine in the ED.[117]

CORTICOSTEROIDS

Parenteral dexamethasone may be administered in cases of intractable migraine.[115] Among a subset of patients experiencing migraine symptoms beyond 72 hours, a greater percentage of patients achieved pain-free status following parenteral dexamethasone administration, relative to placebo.[118] Lower headache recurrence has been observed in patients receiving dexamethasone after standard abortive treatment.[119]

L.P. may be treated with DHE, sumatriptan, prochlorperazine, or metoclopramide because of demonstrated efficacy and tolerability in comparison with other treatment options.[120]

Case 58-1, Question 12: During a return visit to her PCP, L.P. has reported that most migraine episodes have been successfully managed with naratriptan. Although effective, she expresses concern related to episode frequency noting that in some instances, she is using naratriptan three times weekly. Her PCP wants to prescribe propranolol. Is propranolol an appropriate option for L.P.?

Prophylactic Therapy

CRITERIA FOR USE

The relevance of initiating prophylactic therapy for migraine is not simply defined by one common feature among patients. Rather, the impact of migraine for an individual patient needs to be assessed. Targeted outcomes for prophylactic therapy include a reduction in both migraine frequency and severity, enhancing response to acute management strategies, and a general improvement in daily function.[121] Guidance on a patient's suitability for prophylactic management should also address the level of disability associated with episodes, prior experience (success or failure) with acute management modalities, potential for mitigation of adverse effects, and the pathologic complexity of a migraine (eg, basilar or hemiplegic episodes, prolonged auras).[121,122] Among panel recommendations, patients experiencing 6 or more headache days per month were deemed appropriate for prophylactic management.[123] The absolute number of episode days per month is only one parameter to evaluate. It is also important to assess the impact on a patient's daily functioning, as patients may meet criteria for prophylactic management with a lower occurrence of monthly episodes (each episode is associated with a higher level of impairment). Optimizing prophylactic treatment may likely require a 2- to 3-month window. This becomes an important consideration to convey to patients with a focus on maintaining adherence. The evaluation of evidence associated with prophylactic treatments is often challenging because of the lack of studies with comparisons between agents or with crossover design.

PROPRANOLOL

Evidence supports propranolol safety and efficacy in migraine prophylaxis.[121,122,124] Various mechanisms for efficacy may be considered, including the modulation of central catecholamines[125] and interaction with serotonin receptors.[125,126] Propranolol has also demonstrated a suppressive effect on cortical spreading depression

in animal models.[125,127] In a small study of migraine patients, propranolol decreased cerebrovascular reactivity, mediated by action on vascular tone.[128] For L.P., the prescribing of propranolol for migraine prophylaxis could be considered, as there are no contraindications that would prevent use. A limiting variable to continued use may be the adverse effect profile, including lethargy, fatigue, and sleep disruption.[121] As an alternative to propranolol, metoprolol could be considered similarly appropriate for L.P. Comparisons with aspirin[121] or propranolol[121] suggest that metoprolol would be appropriately effective. Metoprolol has been further compared with nebivolol.[129] Although similarly effective in prophylactic migraine management, better tolerability and ease of titration were associated with nebivolol.[129]

Dosing

Initial dosing for propranolol for prophylaxis of migraine headaches is 20 mg by mouth two or three times a day, with gradual weekly titration according to patient tolerability to 80 to 160 mg/day in two to four divided doses.[122] Once the daily dosage of propranolol required to control headaches is established, patient adherence may be improved by changing to a long-acting oral dosage form.

Migraine With Aura

CASE 58-2

Question 1: V.M. is a 24-year-old female who presents for a visit with her PCP and reports a 3-month history of throbbing headaches. Although V.M. has reported experiencing tension-type headaches "on and off" in the past, the character of these recent headaches has been different, accompanied by early-onset, severe nausea and vomiting, and preceded by "flashes of light" and a unilateral facial numbness. The numbness and visual flashes have typically resolved after 30 minutes with headaches developing soon after. She has taken naproxen or ibuprofen for treating recent episodes, but neither has proven effective. The MIDAS score was 11. Medical history includes hypothyroidism treated with levothyroxine 100 µg by mouth daily and a past history of tension-type headache. Her medication profile also includes use of an oral

contraceptive (norgestimate/ethinyl estradiol) for the past 5 years. She describes herself as an occasional smoker and denies a history of alcohol use or illicit substances.

Which information is consistent with the diagnosis of migraine with aura in V.M.?

Although both the “throbbing” character of the headache and associated gastrointestinal (GI) symptoms are consistent with migraine, it is the presence of both the visual (light flashes) and sensory (numbness) disturbances that correlate with the diagnosis of migraine with aura. Relevant information for confirming this diagnosis would be a minimum of two episodes, the accompaniment of an aura symptom, the duration and unilateral nature of the aura, and the evolution of the headache following the aura.[4]

Propagating glial and neuronal depolarization, characterized as cortical spreading depression, has been implicated in aura.[20,130] It is suggested that the pathologic basis for aura involves gap junction modulation at the neuronal level of the trigeminovascular circuitry.[20] Aura has been associated with migraine in approximately one-third of patients,[130] and visual phenomena are typically the most prevalent aura features.[130] It is important to note that visual effects are substantially varied and can include flashing lights, waving lines, or areas of localized blindness (scotoma).[131] A “visual snow” effect has been described in the literature.[132] Although visual phenomena are most prevalent, sensory disturbances (eg, numbness, pins, and needles sensation) may also comprise an aura.[4] In the case of V.M., the aura includes both visual and sensory disturbances, and coupled with the report of additional symptoms (eg, throbbing headache, nausea/vomiting), a diagnosis of migraine with aura is appropriate. The temporal relationship between the aura and evolution of the migraine is one of further consideration. Although V.M. reports the evolution of the migraine following the aura, there is evidence to support classical migraine symptoms occurring during the aura phase.[133]

Case 58-2, Question 2: Should the migraine that V.M. is experiencing be treated according to a stratified-care or step-care model?

In accordance with a step-care model, a conventional analgesic medication would be considered as primary therapy. A stratified-care model would focus on patient effects and characteristics of migraine. V.M. has reported self-treatment with conventional agents (eg, naproxen or ibuprofen) without adequate relief. Further considering that V.M.'s MIDAS score corresponds to "moderate" disability and the reported variance of MIDAS score with age,[33] a stratified-care model would be preferable.

Case 58-2, Question 3: V.M. has been counseled previously regarding the cardiovascular risks associated with oral contraceptives and questions whether she is at greater risk considering her migraine diagnosis. Is an oral contraceptive appropriate for V.M.?

No consistent increased risk for stroke has been found among males, females older than 45 years old, and females who have migraine without aura.[134] Among patients with a diagnosis of migraine with aura, a twofold increase in ischemic stroke risk has been reported.[135] An additional finding in this meta-analysis supported an increased risk among migraine patients using oral contraceptives.[135] The World Health Organization considers migraine with aura in females of any age an absolute contraindication to the use of combined oral contraceptives.[51] The American College of Obstetricians and Gynecologists guidelines permit the use of combined oral contraceptives in females who suffer from migraine with aura as long as they have no focal neurologic signs, do not smoke, and are younger than age 35 years.[51] V.M. describes herself as an occasional smoker, so relevant management strategies include discussing other contraceptive options and a smoking cessation plan.

Case 58-2, Question 4: What is the most appropriate recommendation for acute management of V.M.'s migraine?

Given the severity of symptoms and past treatment experience with conventional analgesics, the selection of a migraine-targeted treatment (eg, ergot alkaloid, triptan) would be preferable. Of similar importance is the presence of severe, early-onset nausea; therefore, nonoral administration is recommended. Sumatriptan and zolmitriptan are available as nonoral formulations, and either could be considered appropriate for V.M. The presence of severe nausea becomes a pivotal factor in treatment selection for V.M. Ergot agents may exacerbate the effect.

Case 58-2, Question 5: V.M. has now returned to her PCP reporting success in managing her migraines with zolmitriptan. The frequency of migraine episodes remains an issue, reporting four to five episodes monthly which have caused her to miss work. Her PCP is considering prophylactic treatment but would prefer not to prescribe propranolol. Which medication may be prescribed to prevent migraines?

AMITRIPTYLINE

Amitriptyline is an appropriate first-line therapy option for migraine prophylaxis[122,136] with such effects being independent of antidepressant activity.[137–139] Mechanistically, therapeutic effects in migraine are imparted via gamma-aminobutyric acid (GABA) receptor upregulation, adenosine modulation, and altering neuronal sensitivity to neuropeptides.[140] Additional effects on the serotonergic system provide further support for tricyclic antidepressant (TCA) benefit in migraine management. Amitriptyline treatment has been associated with significant improvement in MIDAS scores following a 45-day treatment cycle.[141] Particularly applicable to the case of V.M., there is demonstrated benefit for amitriptyline in the treatment of tension-type headache as well,[8] making it a viable option for patients with both headache forms.

Amitriptyline has been compared with propranolol, divalproate, and topiramate in various studies. A randomized trial comparing extended-release divalproate with amitriptyline yielded similar efficacy, measured by headache frequency at 6 months, while being inferior to divalproate at 3 months.[140] Two separate studies have provided comparison between amitriptyline and topiramate.[142,143] With a primary efficacy measure of monthly migraine episode rate, 100-mg doses of each proved comparable and similarly well tolerated.[142] A smaller study reported similar results; however, the combination treatment of amitriptyline and topiramate was assessed as a separate, third treatment arm.[143] Patient satisfaction among subjects taking the combination was noted to be higher relative to either monotherapy group.[143] A comparable response to propranolol has been observed in the evaluation of migraine episode severity and duration.[144] However, in the assessment of rescue medication usage, a more favorable response was noted with propranolol.[144]

Dosing

The initial dose of amitriptyline is 10 to 25 mg by mouth at bedtime. This nightly dose can be increased at weekly intervals by 10 to 25 mg until the maximal dose of 150 mg/day is reached.

Although generally tolerated, common adverse effects attributed to amitriptyline treatment have included drowsiness, anticholinergic effects, and weight increase.[140,142,143] Amitriptyline has been associated with cardiac conduction issues, and there is the potential for patients to experience palpitations and QT prolongation.[145] Patients should be routinely monitored for conduction abnormalities, and alternative treatment options should be considered for patients with cardiovascular concerns.

There is evidence to support the prescribing of other TCAs when intolerance to amitriptyline is observed.[146] The administration of nortriptyline may be considered for patients intolerant to amitriptyline. As a metabolite of amitriptyline, a more favorable adverse effect profile has been observed.[146]

TOPIRAMATE

Topiramate is considered a first-line option for migraine prophylaxis.[122,136] In addition to aforementioned comparisons with amitriptyline, prospective studies have reported similar efficacy between topiramate and sodium valproate.[147–149] Three large randomized, placebo-controlled trials have documented the efficacy of this agent for reducing the number of monthly attacks.[150] With initial dosing of 25 mg daily,[142,143,151] target doses of 100 mg daily[142] and 200 mg daily[151] have been assessed. Evidence supports dose titration to 100 mg for optimal outcomes.[149,152] Further titration to 200 mg has not demonstrated significantly better outcomes relative to 100 mg.[149,153]

Paresthesia, fatigue, weight loss, memory, and concentration deficits have been associated with topiramate therapy.[142,143,154] Research has strengthened the foundation for topiramate-associated alterations in cognition, and such potential should be addressed in consults with migraine sufferers.[155]

VALPROATE

Valproate and divalproex sodium are approved for migraine prophylaxis and are viable treatment options for prevention.[122,136] Results from a prospective trial comparing propranolol and sodium valproate in a small sample of migraine patients suggest greater favorability and a larger response rate with propranolol administration; however, the study did support efficacy of sodium valproate in treating migraines based on duration and severity.[156] Similarities in therapeutic efficacy were observed in comparison with topiramate, as therapeutic end points were not found to be significantly different across treatments.[147] One of the findings of this study was greater favorability with the adverse effect profile of topiramate.[147]

Dosing

Delayed- or extended-release formulations of divalproex sodium may be prescribed for prophylaxis with the advantage of the latter

formulation being once-daily administration. Initial dosing for the delayed-release formulation is 250 mg by mouth twice daily, whereas the extended-release formulation is 500 mg by mouth once daily.

Adverse effects associated with valproate treatment include alopecia, nausea, drowsiness, and weight gain.[148] Incidences of tremor and menstrual irregularities have also been reported.[157] Potential for hepatotoxicity and pancreatitis[158] limits utility.

GABAPENTIN

There is evidence of safety and efficacy in managing migraine patients with gabapentin. Gabapentin administration has yielded reductions in duration, frequency, and migraine severity.[159] The therapeutic benefit needs to be evaluated cautiously, as results from this study reflected greater efficacy with topiramate.[159] Gabapentin enacarbil, a gabapentin prodrug, has been evaluated in the prophylaxis of migraines in dosing levels up to 3000 mg daily but was not associated with significant therapeutic benefit relative to placebo.[160]

CANDESARTAN

Candesartan, an angiotensin II type-1 (AT_1) receptor antagonist, has demonstrated efficacy for migraine prophylaxis in a small randomized, placebo-controlled, crossover trial.[161] Outcomes of migraine frequency (number of days) and duration (number of hours) were favorable with candesartan.[161] Although dizziness was the most frequently reported adverse event associated with treatment, neither this effect nor any other adverse outcome differed significantly from placebo.[161] A 16-mg dose of candesartan was found to have comparable efficacy to a 160-mg propranolol dose in a 12-week clinical trial.[162]

TONABERSAT

As both cortical spreading depression and gap junctional modulation have been linked with migraine aura,[20,130] the inhibition of cortical spreading depression constitutes a potential approach to

treatment.[163] Comparisons with placebo have been mixed[163–165] with efficacy exclusive to migraine with aura.[163] Tonabersat is currently an investigational treatment.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Effectiveness of NSAIDs as preventive therapy is considered modest compared with the first-line agents.[122] NSAIDs may be effective as short-term therapy for menstruation-associated migraine.[122]

In selecting an alternative prophylactic medication for V.M., evidence supports use of selective β-antagonist (eg, metoprolol), amitriptyline, or topiramate. In all such instances, V.M. should be counseled with regard to dose titrations, adverse effects, and allowing for a sufficient trial duration to adequately determine efficacy.

CASE 58-2, QUESTION 6: V.M. has experienced an increase in migraine frequency. She reports 10 to 12 episodes monthly. She reports that headaches have occurred on a consistent basis for at least 5 months. Which treatment options are available for V.M.?

The PREEMPT-2 trial (Phase III REsearch Evaluating Migraine Prophylaxis Therapy) demonstrated onabotulinumtoxin A superiority to placebo in reducing the frequency of headache days.[166] The COMPEL study (Chronic Migraine OnabotulinumtoxinA Prolonged Efficacy Open-Label Study) has provided insight relative to onabotulinumtoxin A efficacy and tolerability for the long-term management of chronic migraine.[167] Administration yielded significant reductions in headache days per month, coupled with improvements observed in HIT-6 scores.[167] Comparable results were obtained in the REPOSE (**RE**al-life use of botulinum toxin for the symptomatic treatment of adults with chronic migraine, measuring healthcare resource utilisation, and **P**atient-reported **O**utcome**S** observed in practice) trial, a nonintervention study assessing patients for 24 months following treatment initiation. A reduction in headache days was observed from a baseline of 20.6 to 7.4.[168] In both trials, adverse effects of neck pain, eyelid ptosis, and muscle

stiffness were reported. Onabotulinumtoxin A is administered via intramuscular injection at a dose of 155 units across 31 injection sites.[169] Monoclonal antibodies are newer therapeutic alternatives in the management of chronic migraine. Four monoclonal antibodies have been FDA approved for the treatment of chronic migraine: eptinezumab, erenumab, fremanezumab, and galcanezumab. There is a slight variation in mechanism among these agents. Erenumab binds to the CGRP receptor, whereas eptinezumab, galcanezumab, and fremanezumab bind to CGRP.[170] The use of monoclonal antibodies is beneficial for patients experiencing inadequate responses to two, or more, established prophylactic treatments.[171] The use of the monoclonal antibodies should also be considered for patients experiencing intolerable adverse effects from other prophylactic treatments.

Erenumab

In a study of nearly 700 patients, two dosing levels (70 and 140 mg) of erenumab were evaluated against placebo. A significant reduction in the number of migraines relative to placebo was observed with both doses.[172] A unique aspect to this study involved the assessment of anti-erenumab antibodies in treated subjects. A larger incidence of antibody presence was noted at the lower dosing level, but a relationship between antibody presence and adverse effects could not be established.[172] Erenumab is administered via subcutaneous injection at doses of 70 and 140 mg once monthly.[173]

Eptinezumab, fremanezumab, and galcanezumab

Efficacy relative to placebo has been observed for fremanezumab in a study assessing both monthly and quarterly administration.[174] Although not statistically significant, there was a slightly better therapeutic outcome observed with monthly administration.[174] There is limited data regarding the utility of such agents for patients with prior treatment failures. The FOCUS trial (A Multicenter, Randomized, Double-Blind, Parallel-Group, Placebo-Controlled Study With an Open-Label Period to Evaluate the Efficacy and

Safety of Fremanezumab for the Prophylactic Treatment of Migraine in Patients With Inadequate Response to Prior Preventive Treatments) yielded results supporting fremanezumab efficacy for those patients with prior treatment failures.[175] Trials of galcanezumab (EVOLVE-1 [Evaluation of LY2951742 in the Prevention of Episodic Migraine], EVOLVE-2, and REGAIN [phase 3, randomized, double-blind, placebo-controlled study of LY2951742 in patients with chronic migraine]) have provided comparable results regarding efficacy versus placebo.[176–178] Efficacy with eptinezumab (PROMISE-2 [Parallel Group, Double-Blind, Randomized, Placebo Controlled Phase 3 Trial to Evaluate the Efficacy and Safety of ALD403 Administered Intravenously in Patients With Chronic Migraine]) has also been demonstrated, with a significant reduction in monthly migraine days versus placebo.[179]

Eptinezumab is administered as an intravenous infusion quarterly.[180] Galcanezumab (monthly) and fremanezumab (monthly or quarterly) are administered by subcutaneous injection. All have been associated with injection site reactions as adverse effects.[180–182] An important consideration for these agents is the eliciting of an immune response.[183,184] The recognition of these proteins by the immune system leads to the generation of neutralizing and anti-drug antibodies, with implications for diminished efficacy.[184] Evidence reflects a greater potential for eptinezumab in facilitating the immunologic response, with nearly 20% of patients developing anti-drug antibodies and 6% of patients developing neutralizing antibodies.[185] The immunologic response reported in studies with erenumab, galcanezumab, and fremanezumab has been lower. Studies with erenumab and galcanezumab have reported anti-drug antibody development in 8% and 11% of subjects and neutralizing antibody formation in 1% and 3% of subjects, respectively.[177,186,187]

Fremanezumab has demonstrated the lowest potential for the formation of anti-drug and neutralizing antibodies.[188,189]

Medication Overuse

CASE 58-3

QUESTION 1: L.D. is a 39-year-old female with a 7-year history of migraine (without aura) and tension-type headache who comes to the clinic requesting a refill of almotriptan. She reports an increase in the frequency of both her throbbing and dull, pressure sensation headaches during the past year, and lately she has had difficulty distinguishing the two types. In the past 2 months, she has had only 5 days with no headache, and she has been much less productive in her work as a magazine editor. She has reported using 4 to 5 almotriptan tablets weekly with multiple episodes also requiring naproxen sodium, which she has purchased over the counter (OTC). She has requested two refills for her almotriptan during the past 1½ months.

What is the role of medication overuse in worsening symptoms, and how should this condition be managed in L.D.?

Medication overuse is defined as the use of triptans, ergot alkaloids, opioid analgesics, or combination analgesics on 10 or more days/month (the criterion for use of simple OTC analgesics is 15 or more days/month)[136] and often occurs in migraine and tension-type headache sufferers.[190] The use of opioids and butalbital-containing products has been associated with a shorter time frame for progression to medication overuse headache. Progression has been associated with butalbital use for 5 or more days per month and with opioid use for 8 or more days per month.[191] The pathophysiology of medication overuse headache is multidimensional and is related to hypometabolism in neuroanatomic structures,[190,192] neurochemical alterations (eg, orexin-A, corticotropin-releasing factor),[193] and alterations in receptor expression and neuropeptide levels (eg, increase in CGRP).[194] There has also been an association between caffeine overuse and morphologic alterations in multiple brain regions.[195]

Chronic daily headaches often have features of both migraine and tension-type headaches.[196]

L.D. displays many of the features of medication overuse headache. She reports an increase in the frequency of headaches to a near-daily pattern, and she is no longer able to distinguish between migrainous and tension-type headaches. Laboratory tests should be ordered to assess L.D.'s renal and hepatic function, and she should

be questioned regarding the occurrence of GI discomfort, acute bleeding, or a change in her stool color.

In general, patients who receive abortive agents for headache treatment should be counseled to restrict their use of these agents to no more than twice per week.[122] The design of medication withdrawal procedures can be tapered or abrupt, with a tapered withdrawal procedure recommended for opioid, barbiturate, or benzodiazepine overuse.[196] Abrupt discontinuation can be considered suitable for triptans and nonopioid analgesics.[196] For L.D., the discussion of a discontinuation strategy would be recommended. Such an intervention has demonstrated positive outcomes in headache reduction.[197,198] Prophylaxis may be considered, and topiramate has demonstrated efficacy in this context.[196,199]

CLUSTER HEADACHE

Cluster headache is characterized by severe, unilateral pain, potentially described as a pulsating or burning sensation, often involving the orbital, temporal, or maxilla regions.[4,200] In addition to pain, cluster headache typically involves autonomic features (eg, miosis, nasal congestion, ptosis, lacrimation).[4,200]

Pathophysiology

The pathology surrounding cluster headache includes stimulation of parasympathetic outflow, disturbance at the level of the hypothalamus, and vasodilation.[201,202] Such pathology is also a function of alterations in testosterone levels,[201] melatonin,[201] and diminished response to thyrotropin-releasing hormone.[201] Further assessments of pineal functioning in the context of cluster headache have revealed anomalies in serial plasma melatonin sampling, reflected as diminished peaks.[203] The pathology further includes

angiographic changes and the interplay of parasympathetic and sympathetic function at the level of the cavernous sinus.[204]

Signs and Symptoms

CASE 58-4

Question 1: R.H. is a 31-year-old male with a 3-year history of episodic cluster headache. He has been headache-free for the past year, but today states that the headaches are returning in their characteristic fashion. He reports abrupt onset of right-sided retro-orbital pain with occasional superimposed knifelike "jabs" that increase in intensity for several minutes to a severe, unrelenting pain lasting about 90 minutes. The headache then gradually subsides. Associated symptoms include right-sided lacrimation, conjunctival injection, and rhinorrhea. He denies any premonition of ensuing headache or GI upset during the attacks. Physical examination during a cluster headache shows right eyelid droop and pupillary miosis. R.H.'s cluster periods characteristically last about 2 months and usually recur once or twice yearly. The first headache of the current episode awoke him from a short nap. R.H. expects to suffer one or two such headaches daily because this has been the usual pattern during each cluster period. Previous cluster headaches have been symptomatically treated with aspirin and codeine 30 mg. However, R.H. reports only modest relief with this treatment approach.

R.H.'s medical history is unremarkable. He does not use tobacco but admits to occasional social drinking.

What subjective and objective evidence in this case is consistent with a diagnosis of cluster headaches?

R.H.'s sex, age of onset, quality and intensity of headache pain, periodicity of headache attacks, and associated symptoms all support the diagnosis of cluster headaches.

An aura may precede a cluster headache episode; however, this effect occurs in a small percentage of patients.[200,205] The episodic timeline of cluster headache is variable, extending from weeks to months, with the potential for extended remission periods.[4] R.H.'s headache quality (severe, unrelenting pain), site (unilateral), evolution and resolution pattern (worsens over several minutes and resolves within 90 minutes), and periodicity of attacks (one or two headaches occurring daily for about 2 months followed by a period of

remission that lasts about 1 year) are all compatible with the usual character of cluster headaches.

Associated symptoms reported by R.H. during headache attacks (eg, lacrimation, rhinorrhea, conjunctival injection) and the absence of GI or neurologic disturbances are also compatible with the cluster headache diagnosis.

CASE 58-4, QUESTION 2: What abortive measures are available for symptomatic treatment of individual headaches during R.H.'s current cluster period?

Abortive Therapy

The treatments of choice for abortive treatment of cluster headaches are sumatriptan by subcutaneous injection, zolmitriptan nasal spray, and oxygen inhalation.[206,207] Among these agents, subcutaneous sumatriptan is often preferred.[208]

SUMATRIPTAN

Sumatriptan 6 mg administered subcutaneously for cluster headaches reduced severity in 74% of attacks within 15 minutes, compared with 26% of attacks treated with placebo.[208] An additional injection of 6 mg does not appear to give additional headache relief.[208] However, in patients who experience a recurrent headache after initial relief with sumatriptan, a second injection is often useful.[202] Sumatriptan should not be used more often than twice daily during cluster bouts.

OXYGEN

High-flow oxygen has demonstrated efficacy in the acute management of cluster headaches and can be used as a first-line treatment option.[209,210] Although the mechanism is not fully understood, there is evidence of inhibited neuronal activation in the trigeminovascular circuit.[211]

Advantages to oxygen treatment include a lack of adverse effects, and a lack of drug interaction potential, allowing for concurrent usage with other treatment options.[212–214] The capacity to administer oxygen treatments multiple times daily represents another advantage in the treatment of cluster headaches.

ZOLMITRIPTAN

Two controlled trials have established the effectiveness of intranasal zolmitriptan for the acute treatment of cluster headache attacks. Cluster headache relief rates were 40% and 50% with 5 mg of zolmitriptan, and 62% and 63% with 10 mg of intranasal zolmitriptan in these two studies, respectively.[207,215]

Reasonable options for the acute treatment of R.H.'s acute cluster headaches include subcutaneous sumatriptan, oxygen inhalation, and intranasal zolmitriptan. For many patients, oxygen is a less convenient therapy because the equipment is not easily portable, and the patient must sit still during the treatment.

Case 58-4, Question 3: What therapeutic agents are available for headache prophylaxis during an active cluster period? Which option is most appropriate for R.H.?

Prophylactic Therapy

Prophylaxis should be considered in the context of chronic cluster headache episodes. In a similar manner to managing migraines, it is important to monitor the use of acute treatment. Instituting prophylactic treatment limits the potential for medication overuse.

VERAPAMIL

Evidence supports verapamil efficacy in cluster headache prophylaxis[200,201,209,216,217] with daily doses in the range of 240 to 320 mg.[201,218,219] Baseline and periodic electrocardiography should be performed for those maintained on verapamil therapy.[200,201] The need

for such monitoring is a function of verapamil's electrophysiologic effects on cardiac nodal tissue.

LITHIUM CARBONATE

Where primary treatment is either ineffective or contraindicated, the use of lithium as a second-line option is supported.[209] There is evidence of direct association with several circadian genes, and there is a direct effect on the retinal-hypothalamic pineal circuitry. The latter effect plays a role in melatonin modulation and impacts sensitivity to light.[220]

Lithium serum levels associated with efficacy in cluster headache prophylaxis are usually between 0.4 and 0.8 mEq/L.[208] In addition to assessing serum levels, routine monitoring of electrolytes, hepatic, renal, and thyroid function is required.[209]

TOPIRAMATE

Topiramate has demonstrated efficacy for cluster headache prophylaxis.[209,221–225] In a study of patients with prior prophylactic treatment exposure, topiramate produced favorable outcomes, inducing remission in > 50% of treated patients.[221]

GALCANEZUMAB

Defining the role of monoclonal antibodies in the prophylaxis of cluster headaches is an area of continued investigation. Galcanezumab has been compared to placebo in the assessment of cluster episode frequency.[226] The administration of galcanezumab did yield a decrease of nearly 9 mean cluster headache episodes over 3 weeks.[226] The decrease in frequency was significant in comparison to placebo.[226] Although a larger volume of research is needed for bolstering the utility of monoclonal antibodies in the therapeutic management of cluster headache, the results support involvement of CGRP in pathogenesis.

Prompt consideration should be given to the aforementioned additional treatments if suppression of headaches during the cluster period is warranted. In general, after response to prophylactic agents

has been established and maintained for at least 2 weeks, attempts can be made to discontinue the drug. Treatment should be reinstituted if headaches recur. With consideration toward patient ease of use and efficacy, treating R.H. with verapamil or topiramate would be rational. Intolerance to such treatment options would support a trial of galcanezumab for R.H.

TENSION-TYPE HEADACHE

Prevalence of tension-type headache is variable but has been shown to be as high as 78%.[4,227,228] Females are slightly more affected by tension-type headaches than males, with a ratio of 5:4.[229] Tension-type headache is typically bilateral and is characterized by milder pain intensity and a tightening quality.[4] Nausea and vomiting are not typical of tension headache presentation but photo- or phonophobia may be present.[4]

Headache frequency is an important determinant for tension-type headache classification, expressed in terms of headache days/month.[4,227] Episodic tension headache can be either infrequent (>1 day/month) or frequent (1–14 days/month), whereas chronic tension headache is classified with a threshold of 15 headache days/month.[4,227]

Pathophysiology

The pathology of tension-type headache is theorized to be a function of both peripheral and central pain pathways, including modulation of trigeminal nociceptors and pericranial muscle strain.[230]

General Management and Abortive Therapy

CASE 58-5

QUESTION 1: K.B., a 27-year-old female financial analyst, presents to her PCP with recurring headaches that worsened when she started her current job. Before this time, she had experienced infrequent headaches, which she associated with periods of stress. The headaches would occur three to four times yearly; were of a constant, dull, or "pressing" character; and were present around the entire head. Recently, headaches of similar character have been occurring about one to two times weekly, usually toward the end of her workday. The pain usually lasts the rest of the day but varies in intensity. Occasionally, a headache is present when she wakes up in the morning. K.B. denies GI and aura symptoms associated with her headaches. She has noticed that relaxation and alcohol ingestion seem to relieve these headaches, but aspirin and acetaminophen have been ineffective. Her blood pressure is 120/74 mm Hg; her physical and neurologic examinations are normal.

What measures should be taken to relieve K.B.'s headaches? What is an appropriate goal for treatment?

K.B. appears to be suffering from frequent episodic tension-type headaches. She reports approximately four to eight headache episodes per month, and these headaches have features that are typical for tension-type headache. As in the treatment of other chronic headache disorders, a cure for recurrent tension-type headache is unlikely. K.B. should clearly understand that the goal of treatment is a reduction in the frequency and severity of headache. Drug therapy and relaxation techniques are the primary means by which tension-type headaches are treated.

ANALGESICS

Conventional analgesics, including NSAIDs, are appropriate first-line treatments for tension-type headache.[227] A meta-analysis of four controlled trials supported the effectiveness of both a combination product (acetaminophen, aspirin, and caffeine) and acetaminophen alone relative to placebo in achieving pain-free status at 2 hours postadministration for tension-type headache treatment.[231] Secondary end points included pain-free status at 1 hour, headache response at 2 hours, and level of impact on daily activity. Improvement in secondary end points was statistically significant for the combination product versus acetaminophen and placebo.[231]

An NSAID (eg, ibuprofen or naproxen) would be an appropriate recommendation for the treatment of K.B.'s tension-type headaches because of her previous inadequate responses to aspirin and acetaminophen.

Case 58-5, Question 2: K.B. was prescribed ibuprofen 400 mg by mouth every 4 to 6 hours as needed for acute relief of recurrent tension-type headaches. At her next scheduled follow-up visit, K.B. reported moderate relief with ibuprofen but with GI upset with each dose, even when taken with food. What prophylactic agents are available for continuous suppression of K.B.'s tension-type headaches?

Prophylactic Therapy

Prophylaxis is relevant in the context of both frequent, episodic tension-type headache and chronic tension headache.[227] Amitriptyline has demonstrated efficacy in managing tension-type headache.[227,232] A median daily dose of 75 mg yielded a significant improvement in headache index relative to placebo.[232] Mirtazapine and venlafaxine have both demonstrated efficacy in tension-type headache treatment relative to placebo.[233,234] Superiority for mirtazapine was demonstrated in measures of headache frequency, intensity, and duration for patients with prior treatment experience.[233]

Given K.B.'s increasing frequency of tension-type headache and her intolerance to moderate doses of ibuprofen, prophylactic treatment with amitriptyline would be appropriate. A starting dose of amitriptyline 10 mg by mouth nightly, increasing by 10 to 25 mg weekly to a maintenance dose of 50 mg/day, should be prescribed, at which time headache response can be assessed and the dose increased or decreased as necessary. If effective, amitriptyline should be continued for 3 to 4 months before gradually decreasing the dose until the drug is completely discontinued. Therapy should be reinstituted if headaches return. Mirtazapine may be initiated as a second-line option for K.B., if amitriptyline is not effective.

Interprofessional Management

Practices in the areas of spiritual meditation,[235] cognitive therapy and stress reduction,[236,237] and acupuncture[238] have been assessed in headache management. A study assessing outcome measures of headache frequency, severity, and medication use, as impacted by spiritual meditation, secular meditation (internally and externally focused), or muscle relaxation, reported a favorable impact on episode frequency induced by spiritual meditation.[235] A decrease in medication usage was similarly reflected in this cohort; however, neither pain sensitivity nor severity differed.[235] Interventions directed toward stress reduction, although deemed feasible, have not met statistical significance for changes in headache severity or frequency.[236] Although stress reduction favorably impacted MIDAS and HIT-6 assessments relative to controls, the study lacked the statistical power to confer significance.[236] Similarly, traditional acupuncture has yielded headache-associated pain relief; however, prospective trials are warranted to better elucidate the therapeutic impact of this practice.[238]

Parkinson Disease and Other Movement Disorders

Shedrick Martin and Kimberly Tallian

CORE PRINCIPLES		CHAPTER CASES
1	Parkinson disease (PD) is a chronic, progressive movement disorder resulting from loss of dopamine from the nigrostriatal tracts in the brain and is characterized by rigidity, bradykinesia, postural disturbances, and tremor.	**Case 59-1 (Question 1, 2)**
2	Treatment for PD is aimed at restoring dopamine supply through one or a combination of the following methods: exogenous dopamine in the form of a precursor, levodopa; direct stimulation of dopamine receptors via dopamine agonists; and inhibition of metabolic pathways responsible for degradation of levodopa.	**Case 59-1 (Question 3–17)**

3	It was once thought to delay the introduction of levodopa with dopamine agonists or monoamine oxidase type B (MAO-B) inhibitors as to avoid peak-dose levodopa-induced dyskinesias as long as possible, but this therapeutic approach has changed more recently, and levodopa/carbidopa should be introduced when early PD is associated with motor symptoms that impact quality of life.	**Case 59-1 (Question 3, 4), Figure 59-1**
4	Initial therapy with levodopa-sparing agents is not associated with a lower risk of developing motor complications than with levodopa. Start with the lowest dose of levodopa to maintain functionality while balancing the development of motor complications.	**Case 59-1 (Question 4–9), Figure 59-1**
5	Advanced PD is characterized by motor fluctuations, including a gradual decline in on-time and by the development of troubling dopaminergic-induced dyskinesias. Modified carbidopa/levodopa formulations, dopamine agonists, MAO-B inhibitors, adenosine A_{2A} receptor antagonist, and catechol-*O*-methyltransferase (COMT) inhibitors can reduce motor fluctuations; amantadine can improve dyskinesias. Deep brain stimulation of the globus pallidus interna or subthalamic nucleus may benefit patients with advanced PD.	**Case 59-1 (Question 13–19), Figure 59-3**
		Case 59-2 (Question

6	Multiple dietary supplements and other investigational therapies have been studied for the management of PD.	1)
7	Comprehensive therapy for patients should include attention to many progressive complications of PD, including neuropsychiatric disturbances and autonomic dysfunction.	Case 59-3 (Question 1, 2)
	RESTLESS LEGS SYNDROME	
1	Restless legs syndrome (RLS) is a disabling sensorimotor disorder typically marked by irresistible urges to move the legs (akathisia). It is often associated with uncomfortable paresthesias or dysesthesias and often occurs in the evening or night.	Case 59-4 (Question 1)
2	Several conditions are associated with or can aggravate RLS. Periodic limb movements of sleep (PLMS) is not the same as RLS but often coexists.	Case 59-4 (Question 2)
3	Dopamine agonists are first-line treatments for RLS. They are preferred because they are longer acting than levodopa and reduce symptoms throughout the entire night. Other effective therapies include carbidopa/levodopa, gabapentin, benzodiazepines, and opiates.	Case 59-4 (Question 3)
4	A common problem with long-term use of dopaminergic agents in RLS, particularly levodopa, is an	Case 59-4 (Question 4)

	augmentation effect. This effect refers to a gradual dosage intensification that occurs in response to a progressive worsening of symptoms after an initial period of improvement. Gradual withdrawal of therapy and substitution with other agents should be performed, rather than continued dopaminergic dose escalation.	
ESSENTIAL TREMOR		
1	Essential tremor (ET) should be distinguished clinically from tremor associated with PD or other causes.	**Case 59-5 (Question 1)**
2	Treatments of choice for ET include propranolol or primidone. In refractory cases, targeted botulinum toxin A injections can be useful.	**Case 59-5 (Question 2)**

INTRODUCTION

Parkinson disease (PD) is a chronic, progressive movement disorder first described in 1817 by Dr. James Parkinson. Since that time, the term parkinsonism has come to refer to any disorder associated with two or more features of tremor, rigidity, bradykinesia, or postural instability.[1] Most cases of PD are of unknown cause and referred to as idiopathic parkinsonism; however, viral encephalitis, cerebrovascular disease, and hydrocephalus have symptoms similar to PD as part of their clinical presentation.[1] Unless otherwise stated, all references to PD in this chapter refer to the idiopathic type.

PD age of onset is variable, increasing after age 50 and peaking around age 80.[2] Both the incidence and prevalence of PD are age-

dependent, with annual incidence estimates ranging from 13.4/100,000 person-years (ages 50–59 years), 58.52/100,000 person-years (ages 60–69 years), 132.72/100,000 person-years (age 70–79 years), and an estimated prevalence of 1% of the population older than age 65 years.[3–5] The overall incidence rate of PD in females 40 years and older is 37.55/100,000 person-years (95% CI: 26.20–53.83) and 61.21/100,000 (95% CI: 43.57–85.99) in males 40 years and older.[5] Males have higher incidence rates than females (70–79 years) with 162.58/100,000 person-years compared to 93.32/100,000 person-years (P = .023).[5] Despite the availability of effective symptomatic treatments to improve both quality of life and life expectancy, no cure exists. The symptoms of PD are progressive and, within 10 to 20 years, significant immobility results for most patients.[6] More rapid rates of symptom progression and motor disability have been observed in patients of older age at disease onset.[7] PD itself does not cause death; however, patients often succumb to complications related to impaired mobility and function (eg, aspiration pneumonia, thromboembolism) and overall frailty.[6]

Etiology

The etiology of PD is poorly understood. Most evidence suggests it is multifactorial and attributable to a complex interplay between age-related changes in the nigrostriatal tract, underlying genetic risks, and/or environmental triggers. Support for this hypothesis can be found in several historic observations.[7]

The relative contributions of environment and genetics to the occurrence of PD remain controversial; rural living, pesticide exposure, and consumption of well water have consistently been associated with increased lifetime risk of PD, whereas exercise, cigarette smoking, and caffeine ingestion appear to be protective.[8,9] Additional risk factors such as mood disorders, head injury, and chronic constipation may contribute to the development of PD.[10] Most cases of PD are sporadic and may be attributed to risk factors over a lifetime. Hereditary PD is thought to be caused by one or

more mutations in 23 Parkinson (*PARK*) genes that have been associated with possible links to the development of PD. Mutations at Parkin RBR E3 ubiquitin protein ligase (PRKN), phosphatase and tensin homolog (PTEN)–induced putative kinase 1 (PINK1), DJ-1, α-synuclein (SCNA), and leucine-rich repeat kinase 2 (LRRK2) vacuolar protein sorting–associated protein 32 (VPS32), and glucocerebrosidase (GBA) show inheritable characteristics. These genes have been reported in 10% to 15% of familial inherited cases of PD, but these genes lack typical Mendelian patterns of inheritance, with occurrence in only about 5% of cases. These heritable factors do not account for the threefold increased risk of developing PD for individuals who have a first-degree relative affected with sporadic PD.[11,12] The exact linkage between genetics, environment, and clinical expression of disease remains uncertain.[13]

Pathophysiology

The salient features of PD result from a loss of dopaminergic neurons in the nigrostriatal tracts of the brain and development of abnormal intraneuronal protein aggregates called Lewy bodies that interfere with neuronal function. The nigrostriatal tracts are neuronal tracts between the substantia nigra and the striatum. They are part of the extrapyramidal system of the brain involving the basal ganglia. This area is involved with maintaining posture and muscle tone by regulating voluntary smooth muscle activity. The pigmented neurons within the basal ganglia have dopaminergic fibers, and in PD, these dopamine-producing neurons are progressively depigmented. The remaining dopaminergic-producing cells have been shown (in postmortem examination) to contain Lewy bodies.[14] Lewy body pathology appears to ascend the brain in a predictable manner in PD, which begin in the medulla oblongata in preclinical stages. These neurologic pathways may explain observations of anxiety, depression, and olfactory disturbance, which ascend to the midbrain (motor dysfunction) and spread eventually to the cortex (cognitive and behavioral changes).[15] The loss of dopamine neurons, either

from death or from dysfunction, results in loss of dopamine-mediated inhibition of acetylcholine neurons. In PD, the typical balance of dopamine and acetylcholine is lost, which results in a relative increase in cholinergic activity.

The exact pathologic sequence leading to neurodegeneration is unclear, but free radicals formed as byproducts of dopamine auto-oxidation, cell apoptosis, protein misfolding and aggregation, defective proteolysis, oxidative stress and iron metabolism, and mitochondrial dysfunction have all been implicated. The finding that a critical threshold of neuronal loss (at least 70%–80%) occurs before PD becomes clinically apparent suggests that adaptive mechanisms (eg, upregulation of dopamine synthesis or downregulation of synaptic dopamine reuptake) may somehow influence disease progression during the preclinical stages.

Clinical Presentation of Parkinson Disease

CASE 59-1

Question 1: L.M., a 55-year-old, right-handed male artist, presents to the neurology clinic reporting difficulty painting because of unsteadiness in his right hand. He also endorses a loss in the sense of smell. His medical history is significant for gout (currently requiring no treatment), constipation (ie, progressively worsened in the past 10 years), benign prostatic hypertrophy, depression, and aortic stenosis. He does not smoke but usually drinks one alcoholic beverage in the evenings. His only prescription medication is citalopram 10 mg by mouth once daily. On physical examination, L.M. is noted to be a well-developed, well-nourished male who displays a notable lack of normal changes in facial expression but speaks in a soft, monotone voice. He lacks rigidity in both of his arms or legs but is noted to have a mild resting tremor in his right hand. His gait is slow but otherwise normal with a slightly bent posture. His balance is normal with no retropulsion or loss of righting reflexes after physical threat. His genitourinary examination is remarkable only for prostatic enlargement. The remainder of his physical examination is within normal limits. Laboratory values and vital signs obtained at this visit include the following:

Blood pressure, 119/66 mm Hg
Heart rate, 71 beats/minute
Sodium, 132 mEq/L

Potassium, 4.4 mEq/L
Blood urea nitrogen, 19 mg/dL
Creatinine, 1.1 mg/dL
Thyroid-stimulating hormone, 3.65 μU/L
Vitamin B_{12}, 612 pg/mL
Folate, 5.2 ng/mL
White blood cells, 4400 cells/mL
Red blood cells, 5.9×10^6/mL
Hemoglobin, 13.8 g/dL
Hematocrit, 41%
Uric acid, 6.3 mg/dL

How is PD best diagnosed? Is neuroimaging or any other testing recommended in the diagnosis of PD? What early signs and symptoms suggestive of PD are present in L.M.? What symptoms are among the classic features seen in PD?

The diagnosis of PD remains firmly grounded in obtaining a careful history and physical examination.[14] The neurologic examination to assess motor function, along with a positive response to levodopa, is highly diagnostic. The search for biomarkers of premotor PD in blood, cerebrospinal fluid, and urine has not uncovered single, practical candidates that are sensitive and specific.[11] Likewise, although imaging techniques can visualize nigrostriatal nerve terminals of dopamine synthesis and identify presymptomatic pathology, their routine use in asymptomatic, at-risk individuals is not yet recommended. In some instances, 123I-ioflupane (123I-FP-CIT) single-photon emission computed tomography (SPECT) scanning can be considered in clinical diagnosis of patients where there is uncertainty between PD and nondegenerative parkinsonism or tremor disorders. Other associated premotor symptoms, such as constipation, hyposmia (a reduced ability to smell and detect odors), rapid eye movement (REM) sleep disorder, and softening as well as tonal changes of the voice are among the earliest symptoms to appear. Screening for these findings may prove more economically practical in identifying a high-risk population worthy of further diagnostic evaluation.[16] However, by the time patients such as L.M. present with early symptoms, some burden of neuropathologic

evidence has accumulated, and, therefore, a diagnosis can be made clinically without the need for further laboratory or radiologic testing.

The classic features of PD—tremor, limb rigidity, and bradykinesia — are easily recognized particularly in advanced stages of the disease. Limb rigidity and bradykinesia are direct consequences of dopamine loss by disinhibiting cholinergic transmission whereby dopamine loss indirectly causes tremor. It is important to note that not all classic features are required to make the diagnosis of PD. The presence of two or more features indicates clinically probable PD.[17] Tremor, which is most often the first symptom observed in younger patients, is usually unilateral on initial presentation. Frequently, the low-amplitude tremor is of a pill-rolling type involving the thumb and index finger (3–6 Hz). The tremor is present at rest, worsens under fatigue or stress, and is absent with purposeful movement or when asleep.[1] These features help distinguish it from essential tremor (ET), which usually manifests as a symmetric tremor in the hands, often accompanied by head and voice tremor.[14] Approximately 20% of patients with PD do not present with tremor.[14] Muscular rigidity, resulting from increased muscle tone, often manifests as a cogwheel or ratchet (catch-release) type of motion when an extremity is moved passively.[1] Rigidity may also be experienced as stiffness or vague aching or limb discomfort.[14] Bradykinesia refers to an overall slowness in initiating movement. Early in the disease, patients may describe this as weakness or clumsiness of a hand or leg.[14] Because the disease progresses, difficulty initiating and terminating steps results in a hurried or festinating gait; the posture becomes stooped (simian posture), and postural reflexes are impaired.[1] Symptoms that were unilateral on initial presentation progress asymmetrically and often become bilateral as well as more severe with disease progression.[1] Patients with PD may develop masked facies or a blank stare with reduced eye blinking.

Because the diagnosis of PD is clinical, misdiagnosis can occur, leading to inappropriate, ineffective, or delayed treatment. Several conditions can be mistaken for PD and are important to distinguish from PD because they respond poorly to dopaminergic medications

and are associated with worse prognosis.[14] Falls or dementia early in the disease, symmetric parkinsonism, wide-based gait, abnormal eye movements, marked orthostatic hypotension, urinary retention, or marked disability within 5 years after the onset of symptoms suggest alternative diagnoses to PD.[14] Drugs may also mimic idiopathic PD. Drugs that act as antagonists at dopaminergic D_2 receptors (eg, neuroleptics, prochlorperazine, and metoclopramide), and others such as valproate, amiodarone, lithium, carbamazepine, and phenytoin (least) may cause a state of drug-induced parkinsonism or tremor. This potential etiology should be excluded before the diagnosis of PD is established. Although generally reversible, symptoms may persist for weeks or months after discontinuation of the offending agent.[14]

L.M. initially presents with classic premotor features such as his soft, monotone voice, reduced sense of smell, and constipation in addition to the classic symptoms of PD. A noticeable unilateral resting tremor is present along with decreased manual dexterity, as evidenced by his difficulty handling a paintbrush. Handwriting abnormalities occur frequently, particularly micrographia, a symptom of bradykinesia. Because L.M. is an artist, this abnormality would be particularly troublesome. Although he has a partially stooped posture, it is difficult to attribute this entirely to the disease because postural changes commonly occur with advancing age and, on physical examination, his balance was normal. To confirm the diagnosis of PD, a therapeutic trial of medication (levodopa) should be considered. A positive response to levodopa, as evidenced by an improvement in motor function, suggests the diagnosis of PD. However, patients with the tremor-predominant form of the disease may not respond to levodopa, especially in the early stages of the disease.[14]

Staging of Parkinson Disease

Case 59-1, Question 2: What are the four stages of PD? In what stage of PD is L.M. in?

To assess the degree of disability and determine the rate of disease progression relative to treatment, various scales have been developed. The most common of these is the Hoehn and Yahr scale (**Table 59-1**) and the modified Hoehn and Yahr scale.[2] In general, patients in Hoehn and Yahr[2] stage 1 or 2 of PD have mild disease that does not interfere with activities of daily living (ADLs) or work and usually requires minimal or no treatment. In stage 3 disease, daily activities are restricted, and employment may be significantly affected unless effective treatment is initiated. According to the scale, L.M. appears to be in late stage 2, early stage 3 of the disease (early symptomatic PD).

Table 59-1
Staging of Disability in Parkinson Disease

Stage 1	Unilateral involvement only; changes in posture, walking, and facial expressions occur; minimal or no functional impairment
Stage 2	Bilateral involvement, without impairment of balance; walking problems and poor posture may be apparent
Stage 3	Evidence of postural imbalance and slowness of movement; some restriction in activities; capable of leading independent life; mild-to-moderate disability such as dressing and eating
Stage 4	Severely disabled, possibility can stand without assistance but cannot walk and stand unassisted; significantly incapacitated required help needed for activities of daily living and is unable to live alone
Stage 5	Stiffness in the legs making it impossible to stand or walk; restricted to bed or wheelchair unless aided; experience hallucinations and delusion where both motor and nonmotor symptom management are needed

Source: Ascherio A, Schwarzschild MA. The epidemiology of Parkinson's disease: risk factors and prevention. *Lancet Neurol.* 2016;15(12):1257–1272.

With advanced-stage disease (stages 3 and 4), most patients require a double- or triple-drug therapy strategy. Patients with end-stage disease (stage 5) are severely incapacitated and, because of advanced disease progression, often do not respond well to drug therapy.

Treatment of Parkinson Disease

OVERVIEW OF THERAPY

Numerous national and international guidelines exist regarding the management of motor and nonmotor symptoms of PD. These guidelines include the American Academy of Neurology (AAN) practice parameters developed in 2002 and 2006,[18,19] the United Kingdom National Institute for Health and Care Excellence (NICE) national guideline developed in 2006 and revised in July 2017,[20] the European Federation of Neurological Societies Movement Disorder Society-European Section (EFNS MDS-ES) guidelines developed in 2016,[21] and the Canadian guideline for Parkinson disease in 2019.[22]

Although most of this chapter is devoted to the drug therapy of PD, the importance of nonpharmacologic, supportive care cannot be overemphasized. Patients in early PD stages should be enrolled in rehabilitative services to improve balance and motor function. These therapies include exercise, physical and occupational therapy, yoga, and speech therapy. Additionally, dietary recommendations of increased protein and vitamin D can be beneficial at the earlier stages to increase strength and enhance well-being and mood.[20] Psychological support is often necessary in dealing with depression and other related problems. Patients who are newly diagnosed and their family members need to be educated about what to expect from the disease and the various forms of treatment available. The support of family members is vital in establishing an overall effective therapeutic plan.

Nonpharmacologic therapy should continue throughout the course of care; however, because of the progressive nature of PD, pharmacologic therapy is often necessary. Because the salient pathophysiologic feature of PD is the progressive loss of dopamine from the nigrostriatal tracts in the brain, drug therapy for the disease is aimed primarily at replenishing the supply of dopamine. This pharmacologic intervention is accomplished through one, or a combination, of the following methods: (a) administering exogenous dopamine in the form of a precursor, levodopa; (b) stimulating dopamine receptors within the striatum through the use of dopamine

agonists (eg, pramipexole, ropinirole); or (c) inhibiting the major metabolic pathways within the brain that are responsible for the degradation of levodopa and its metabolites. This latter effect is achieved by using aromatic L-amino acid decarboxylase (AAD) inhibitors (eg, carbidopa), catechol-*O*-methyltransferase (COMT) inhibitors (eg, entacapone), or monoamine oxidase type B (MAO-B) inhibitors (eg, selegiline, rasagiline). Anticholinergics are also used; however, they are solely efficacious for the cholinergic-mediated tremor, and their routine use is limited by physical side effects (eg, blurry vision, constipation) and central nervous system (CNS) adverse effects, particularly in older patients. Amantadine is also used occasionally and may provide modest benefits via both dopaminergic and nondopaminergic (inhibition of glutamate) mechanisms (**Table 59-2**). A unique agent, istradefylline, works as an adenosine A_{2A} receptor antagonist that has shown benefit as an adjunctive therapy for levodopa "off" time. Because PD progresses, additional options, such as surgery, may be appropriate for a subset of patients.

Table 59-2
Medications Used for the Treatment of Parkinson Disease

Generic (Trade) Name	Dosage Unit	Titration Schedule	Usual Daily Dose	Adverse Effects
Amantadine (Symmetrel®)	100-mg capsule and tablet Liquid: 50 mg/5 mL 68.5- and 137-mg ER capsule 129-, 193-, and 258-mg ER tablet	IR capsule, tablet, liquid: 100 mg every day; increased by 100 mg every 1–2 weeks ER capsule: 137 mg every day; increased by 137 mg every week ER tablet: 129 mg every day; increased by 129 mg every week	IR capsule, tablet, liquid: 100–400 mg ER capsule: 274 mg ER tablet: 129–322 mg	Orthostatic hypotension, insomnia, depression, hallucinations, livedo reticularis, xerostomia
Anticholinergic agents				
Benztropine (Cogentin)	0.5-, 1-, and 2-mg tablets Injection: 1 mg/mL	0.5 and 1 mg at bedtime or in two to four divided doses increased by 0.5 mg every 5–6 days	1–3 mg given every day to bid	Constipation, xerostomia, dry skin, dysphagia, confusion, memory impairment
Trihexyphenidyl (Artane)	2- and 5-mg tablets Liquid: 2 mg/5 mL	1–2 mg/day increased by 1–2 mg every 3–5 days	6–10 mg divided tid to qid	Constipation, xerostomia, dry skin, dysphagia, confusion, memory impairment
Combination agents				
Carbidopa–levodopa (IR)/entacapone (Stalevo®)	12.5-/50-/200-, 18.75-/75-/200-, 25-/100-/200-, 31.25-/125-/200-, 37.5-/150-/200-, 50-/200-/200-mg tablets	Titrate with individual dosage forms (carbidopa/levodopa and entacapone) first, then switch to combination tablet	Varies (see individual drugs)	See individual drugs; <70–100 mg daily of carbidopa component may experience nausea and vomiting
Dopamine replacement				
Carbidopa–levodopa (IR) (Sinemet®)	10-/100-, 25-/100-, and 25-/250-mg tablets	25/100 mg bid, increased by 25/100 mg weekly to effect and as tolerated	30/300 to 150/1500 mg divided tid to qid	Nausea, orthostatic hypotension, confusion, dizziness, hallucinations, dyskinesias, blepharospasm
Carbidopa–levodopa (CR) (Sinemet® CR)	25-/100- and 50-/200-mg tablets	25/100 mg bid (spaced at least 6 hours apart), increased every 3–7 days	50/200 to 500/2000 divided qid	Same as regular Sinemet®
Carbidopa–levodopa (ER) (Rytary®)	23.75-/95-, 36.25-/145-, 48.75-/195-, 61.25-/245-mg capsules	23.75/95 mg tid; may increase to 36.25/145 mg tid on day 4 and titrate to response	Variable	Same as regular Sinemet®
Carbidopa–levodopa (enteral suspension) (Duopa™)	4.63-/20-mg/mL in 100-mL cassette	Total daily dose administered over 16 hours	Variable	Same as regular Sinemet®
Carbidopa–levodopa ODT (Parcopa®)	10-/100-, 25-/100-, and 25-/250-mg tablets	25/100 tid, increased every 1–2 days; if transferring from regular levodopa <1500 mg/day, start 25/100 mg tid to qid (start 25/250 mg tid to qid if already on >1500 mg/day of regular levodopa)	25/100 to 200/2000 divided tid to qid	Same as regular Sinemet®; may occur more rapidly than with regular Sinemet®
Levodopa inhaled (Inbrija®)	42-mg capsule per inhalation	84 mg up to five times daily as needed	84–420 mg	Cough, upper respiratory tract infection, discolored sputum, hallucinations, confusion, nausea, dyskinesias
Dopamine agonists				
Bromocriptine (Parlodel®)	2.5-mg tablet, 5-mg capsule	1.25 mg bid, titrate slowly as tolerated (2.5 mg/day every 2–4 weeks)	10–40 mg divided tid; max 100 mg/day	Orthostatic hypotension, confusion, dizziness, hallucinations, nausea, muscle cramps; retroperitoneal, pleural, pericardial fibrosis; cardiac valve thickening

Pramipexole (Mirapex®, Mirapex® ER)	IR: 0.125-, 0.25-, 0.50-, 0.75-, 1-, 1.5-mg tablets ER: 0.375-, 0.75-, 1.5-, 2.25-, 3-, 3.75-, 4.5-mg tablets	IR: 0.375 mg divided tid; titrate 5 to 7 days by 0.125–0.25 mg/dose ER: 0.375 mg once daily; titrate 5–7 days by 0.75 mg/dose	Immediate release: 1.5–4.5 mg divided tid ER: 1.5–4.5 mg once daily	Orthostatic hypotension, confusion, dizziness, hallucinations, nausea, somnolence
Ropinirole (Requip, Requip XL)	0.25-, 0.5-, 1-, 2-, 3-, 4-, 5-mg tablet XL: 2-, 4-, 6-, 8-, 12-mg tablets	0.25 mg tid; titrate weekly by 0.25 mg/dose XL: 2 mg once daily; titrate weekly or longer intervals by 2 mg/day	3–24 mg divided tid XL: 3–24 mg once daily	Orthostatic hypotension, confusion, dizziness, hallucinations, nausea, somnolence
Apomorphine (Apokyn®), (Kynmobi™)	10 mg/mL injection; 10-, 15-, 20-, 25-, 30-mg sublingual film	Initial 2-mg subcutaneous test dose; begin with 2 mg; increase by 1 mg every few days Concomitant trimethobenzamide should be begun 3 days prior to initial oral dose; initial dose 10-mg	2–6 mg 10–30 mg	Orthostatic hypotension, drowsiness, yawning, injection site reactions, nausea, vomiting (administer with trimethobenzamide, not 5-hydroxytryptamine-3 [5-HT_3] antagonists)
Rotigotine (Neupro®)	1-, 2-, 3-, 4-, 6-, 8-mg/24-hour transdermal delivery system	Early stage: 2 mg/24 hour; advanced stage: 4 mg/24 hour; titrate weekly by 2 mg/24 hour; application site should be rotated daily between abdomen, thigh, hip, flank, shoulder, or upper arm and do not use same site within 14 days	Early stage: 4–6 mg/24 hour Advance stage: 4-8 mg/24 hour	Hallucinations, nausea, vomiting, anorexia, somnolence, insomnia, dizziness, hyperhidrosis, visual disturbance, peripheral edema, and application site reactions; avoid in patients with known sulfite sensitivity
Catechol-O-methyltransferase inhibitors				
Entacapone (Comtan®)	200-mg tablet	200 mg with each administration of carbidopa/levodopa, up to 1600 mg daily	600–1600 mg daily	Diarrhea, dyskinesias, abdominal pain, urine discoloration
Tolcapone (Tasmar®)	100-mg tablet	100 mg tid	300–600 mg divided tid	Diarrhea, dyskinesias, abdominal pain, urine discoloration, hepatotoxicity
Opicapone (Ongentys®)	25-, 50-mg tablets	N/A	50 mg/day	Dyskinesia, constipation, hypotension, syncope, weight decrease
Monoamine oxidase type B inhibitors				
Rasagiline (Azilect®)	0.5-, 1-mg tablets	0.5–1 mg once daily	0.5–1 mg/day	Similar to selegiline
Safinamide (Xadago™)[a]	50-, 100-mg tablets	50 mg once daily; dose may be increased after two weeks to 100 mg once daily	50–100 mg/day	Similar to selegiline
Selegiline (Eldepryl®)[b]	5-mg tablet, capsule	5 mg every morning; may increase to 5 mg bid (5 mg with breakfast and 5 mg with lunch)	5–10 mg/day	Insomnia, dizziness, nausea, vomiting, xerostomia, dyskinesias, mood changes; use caution when coadministered with sympathomimetics or serotoninergic agents (increased risk of serotonin syndrome); avoid tyramine-containing foods

Selegiline ODT (Zelapar®)	1.25-mg tablet	1.25 mg every day; avoid food or liquids for 5 minutes before and after administration; may increase to 2.5 mg every day after 6 weeks	1.25–2.5 mg every day	Insomnia, dizziness, nausea, vomiting, xerostomia, dyskinesias, mood changes; use caution when coadministered with sympathomimetics or serotoninergic agents (increased risk of serotonin syndrome); avoid tyramine-containing foods
Adenosine receptor antagonist				
Istradefylline (Nourianz®)	20-, 40-mg tablets	20 mg once daily; dose may be increased up to 40 mg once daily	20–40 mg/day	Dyskinesia, constipation, nausea, hallucinations, insomnia

[a]Approved only for use as adjunctive treatment to levodopa/carbidopa in patients experiencing "off" episodes.

[b]A transdermal formulation is also available, but not approved for use in PD.

bid, twice daily; CR, controlled release; COMT, catechol-*O*-methyltransferase; ER, extended release; IR, immediate release; MAO-B, monoamine oxidase type B; ODT, orally disintegrating tablet; qid, four times daily; tid, three times daily; XL, extended release.

Despite optimization of both pharmacologic and nonpharmacologic therapies in PD, physical disability is progressive and unavoidable. In many instances, adverse effects of the medications themselves can lead to additional problems. These include neuropsychiatric problems (eg, cognitive impairment and dementia, hallucinations and delirium, depression, agitation, anxiety), autonomic dysfunction (eg, constipation, urinary problems, sexual problems, orthostasis, thermoregulatory imbalances), falls, sleep disorders (eg, insomnia or sleep fragmentation, nightmares, restless legs syndrome [RLS]), and motor complications (eg, disabling periods of either too much [dyskinetic] or too little [akinetic] dopaminergic activity).

Treatment of Early Parkinson Disease

Case 59-1, Question 3: What factors would indicate L.M. should begin treatment for his PD?

In choosing when to treat the symptoms of PD and which therapy to use, care must be taken to approach each patient individually. Although no consensus has been reached about when to initiate

symptomatic treatment, most clinician's agree that treatment should begin when the patient begins to experience functional impairment or impact quality of life as defined by (a) threat to employment status, (b) symptoms affecting the dominant side of the body, or (c) bradykinesia or rigidity.[23,24] Individual patient preferences also should be considered. Judging by the symptoms L.M. is displaying, he would likely benefit from immediate treatment. His symptoms are unilateral but are occurring on his dominant side and are interfering with his ability to paint, thus affecting his livelihood. He is also showing signs of rigidity and bradykinesia but can otherwise live independently. An algorithm for the management of patients with early PD is presented in **Figure 59-1**. The long-term, individualized treatment plan is usually characterized by frequent dosage adjustments because of the chronic and progressive nature of the disease.

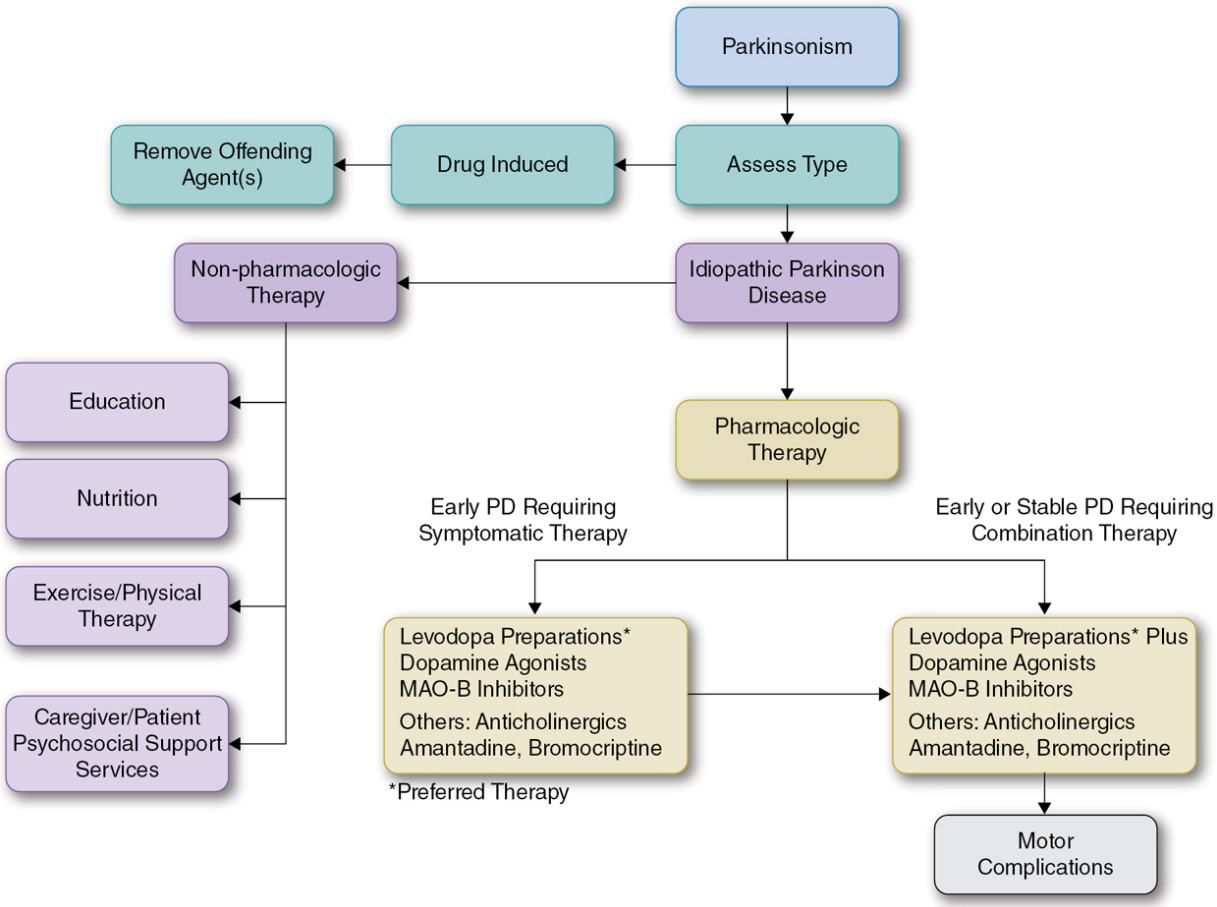

Figure 59-1 Suggested treatment algorithm for the management of early Parkinson disease. MAO, monoamine oxidase; PD, Parkinson disease.

CASE 59-1, QUESTION 4: The decision is made to begin drug therapy for L.M. Should therapy be initiated with a levodopa or levodopa-sparing therapy? What characteristics assist in selecting the initial treatment of choice for L.M.?

Despite advances in pharmacologic treatment options for PD, no therapy has been proven to be disease-modifying or neuroprotective. Therapy continues to be symptomatic, and levodopa remains the most effective antiparkinsonian agent.[20] Based on multiple guidelines, levodopa should be used first line at the lowest effective dose while balancing the long-term risks of motor fluctuations and dyskinesias.[20–22] There are two levodopa-sparing methods that may be used instead of or in combination with levodopa: dopamine agonists (ie, motor PD complications) and MAO-B inhibitors (ie, extend on-time and reduce off-time).[22] Both of these modalities have proven efficacy early in early PD.[20]

Dopamine agonists, which bind directly to dopamine receptors, do not require metabolic conversion to an active product and, therefore, act independently of degenerating dopaminergic neurons. In clinical trials comparing dopamine agonists with levodopa, ADLs and motor features are improved to a greater degree with levodopa compared with dopamine agonists.[21] Although they are not as effective as levodopa, the dopamine agonists have potential advantages. Unlike levodopa, circulating plasma amino acids do not compete with dopamine agonists for absorption and transport into the brain, which eliminate administration constraints. Dopamine agonists have a longer half-life than levodopa formulations, which reduce the need for multiple daily dosing. As a class, dopamine agonists provide adequate control of symptoms when given as monotherapy in up to 80% of patients with early-stage disease.[25]

Short- and long-term comparisons of patients with early disease started on either levodopa or dopamine agonists have varying

results. In trials extending 4 to 5 years, therapy with dopamine agonists is associated with fewer motor complications such as dyskinesias, delayed time to dyskinesias, and delayed need for initiation of dopaminergic therapy.[26–28] As opposed to levodopa as initial therapy, early trials of the dopamine agonists appear to delay the onset of dyskinesias. In a randomized, controlled trial evaluating the development of motor complications with levodopa or the dopamine agonist pramipexole, 301 untreated patients with early PD were randomly assigned to receive either pramipexole 0.5 mg three times daily or carbidopa/levodopa 25/100 mg three times daily.[28] Patients in both arms could be prescribed open-label levodopa as needed for disability during the maintenance phase of the study. After a mean follow-up of 24 months, fewer patients who are treated with pramipexole reached the primary endpoint of time to the first occurrence of wearing-off, dyskinesias, or on–off motor fluctuations (28% vs 51%; $P < .001$) than the patients initially randomly assigned to levodopa therapy. Additionally, patients in the pramipexole group were receiving lower daily doses of levodopa, theoretically conferring a reduced risk of developing motor complications. Long-term follow-up of this cohort (mean = 6 years) revealed a persistently lower rate of dopaminergic motor complications in the pramipexole-treated patients compared with those receiving levodopa (50% vs 68.4%, respectively; $P = .002$).[29]

Despite the continued increased risk of motor complications in patients started on levodopa, trials extending 10 to 15 years found no significant difference in disease severity rating or rates of disabling dyskinesias.[30,31] Patients treated initially with ropinirole were less likely to experience dyskinesias compared with those treated initially with levodopa at the end of a 5-year evaluation.[26] Patients in the ropinirole group used lower mean daily doses of levodopa (427 mg vs 753 mg) but were almost twice as likely to need open-label levodopa supplementation (66% vs 36%). Dyskinesias developed in 20% of the ropinirole-treated patients compared with 45% of the levodopa-treated patients. For ropinirole-treated patients who were able to remain on monotherapy without open-label levodopa supplementation, only 5% experienced

dyskinesia, compared with 36% of those receiving levodopa monotherapy. Although the lower incidence of dyskinesias was shown to persist in a long-term open-label follow-up of this study cohort, there was no difference in disease severity between the ropinirole-treated group and the levodopa-treated group at 10 years.[30] There may be additional trends toward better cognitive and health-related quality of life outcomes in the patients started on levodopa.[31] This result may be due in part to the fact that although dopamine agonists may delay motor complications and are not without side effects, trials have consistently shown higher rates of adverse drug reactions in patients initially started on dopamine agonists.[26,28] One open-label, randomized trial found that 28% of patients discontinued initial therapy with dopamine agonists because of side effects versus only 2% of patients initially given levodopa.[31]

MAO-B inhibitors are an alternative method of enriching dopamine supply in early disease. These agents increase nigrostriatal dopamine supply via the irreversible inhibition of MAO-B, a major enzymatic pathway responsible for the metabolism of dopamine in the brain, require the presence of dopamine for clinical effect.[32] Although MAO-B inhibitors have been shown to delay the need for dopaminergic therapy with levodopa, definitive efficacy comparisons are lacking.[32]

Early guidance from the AAN and EFNS MDS-ES supports either dopamine agonists or levodopa as initial therapy for PD; however, Canadian and NICE, and EFNS MDS-ES guidelines support the use of MAO-B inhibitors in initial therapy, whose motor symptoms affect their quality of life, levodopa should be initiated.[18–22] The long-term effectiveness of dopamine agonists and MAO-B inhibitors compared with levodopa as initial treatment for PD (PD MED) trial set out to compare and contrast levodopa versus levodopa-sparing therapies.[33] Patients assigned to monotherapy with MAO-B inhibitors or dopamine agonists were generally younger and healthier than those assigned levodopa as initial therapy. At 7-year follow-up, 72% of patients initially assigned to MAO-B inhibitors withdrew from initial therapy and changed treatment compared to 50% in the dopamine agonist group and 7% in the levodopa group ($P < .0001$). Among

those patients initiated on MOA-B inhibitors, 23% withdrew because of side effects and 17% withdrew because of lack of efficacy, and for patients initiated on dopamine agonists, 28% withdrew because of side effects and 6% withdrew because of lack of efficacy.[33] As shown in prior studies, levodopa improved function and quality of life to a greater degree; however, the primary mobility outcome did not reach the prespecified minimal difference. Mobility scores were not significantly different between MAO-B inhibitors and dopamine agonists, indicating that MAO-B inhibitors are at least as effective as dopamine agonists in early therapy of PD.[33] Additionally, at 7 years, patients on dopamine agonists were on the highest overall amount of medication. The study confirms that initial treatment with a dopamine agonist, MAO-B inhibitor, or levodopa may all be reasonable approaches.

Disease severity, degree of functional impairment, life expectancy, and age guide therapeutic drug selection in early PD. In milder disease, such as L.M., the initiation of levodopa or a levodopa-sparing therapy (either a dopamine agonist or MAO-B inhibitor) would be appropriate. Although the PD MED trial did conclude that MAO-B inhibitors are at least as effective as dopamine agonists for initial therapy, other meta-analyses show that the degree of symptomatic benefit over placebo is small in comparison with those of dopamine agonists over placebo.[34] Overall, there is a lack of comparative data between MAO-B inhibitors and dopamine agonists. Therefore, use of MAO-B inhibitors in initial therapy is often limited to young patients with more mild functional impairments. With more significant functional impairments or with limited life expectancy, use of levodopa may be warranted as the benefit (ie, symptomatic benefits) outweighs the risk (ie, relatively high risk of motor complications and side effects) compared to levodopa-sparing therapy. Additionally, levodopa may be more appropriate initial treatment in older patients as they may be more likely to experience intolerable CNS side effects from dopamine agonists as well as are less likely to develop motor complications over their lifetime.[23]

In the case of L.M., his relatively young age, mild disease, and moderate functional impairments make him a good candidate for

initial therapy with low-dose levodopa. When more advanced stages of disease are reached, L.M. will require levodopa therapy later. By initiating therapy first with a dopamine agonist, rescue levodopa therapy can likely be started at smaller doses, and the onset of motor complications that often occur with escalating doses as well as extended therapy with levodopa may be delayed.

DOPAMINE AGONISTS

CASE 59-1, QUESTION 5: L.M. is to be initiated on a dopamine agonist for L.M.'s concern that levodopa will worsen his insomnia. He discloses he has had an extensive sleep disorder worked up and gets about 5 hours of sleep each night despite trying melatonin, doxepin, and trazodone without improvement. Additionally, his neurologist feels his insomnia is related to his PD motor symptoms. Which agent should be selected?

Two generations of dopamine agonists have been used for the treatment of idiopathic PD in early-stage PD as monotherapy or as an adjunct to levodopa in patients with advanced disease. The comparative pharmacologic and pharmacokinetic properties of these agents are shown in **Table 59-3**. The first-generation dopamine agonists, which are derived from ergot alkaloids, include bromocriptine, pergolide, and cabergoline. These older agents are now rarely used because of increased risk of retroperitoneal, pleural, and pericardial fibrosis as well as a two- to fourfold increased risk for cardiac valve fibrosis when compared with nonergoline dopamine agonists and controls.[35,36] Pergolide was voluntarily withdrawn in the United States in 2007 for this reason, and although cabergoline continues to be used in Europe, it is only indicated in the United States for the treatment of hyperprolactinemia. Pramipexole, ropinirole, apomorphine, and rotigotine are second-generation nonergoline dopamine agonists. Of these agents, pramipexole and ropinirole are commonly prescribed. Apomorphine is available as an injectable and sublingual film for use as a rescue agent in the treatment of hypomobility "off" episodes in patients with PD.

Rotigotine, a once-daily transdermal formulation, was recently reintroduced into the market.

Table 59-3
Pharmacologic and Pharmacokinetic Properties of Dopamine Agonists

	Bromocriptine	Pramipexole	Ropinirole	Apomorphine	Rotigotine
Type of compound	*Ergot derivative*	*Nonergoline*	*Nonergoline*	*Nonergoline*	*Nonergoline*
Receptor specificity	D_2, D_1,[a] α_1, α_2, 5-HT	D_2, D_3, D_4, α_2	D_2, D_3, D_4	D_1, D_2, D_3, D_4, D_5, α_1, α_2, 5-HT_1, 5-HT_2	D_1, D_2, D_3, 5-HT_1
Bioavailability	7% (extensive first-pass metabolism)	Immediate release (IR): 90%; extended release (ER): 100%	55% (first-pass metabolism)	<5% orally; 100% subcutaneous	<1% (hip and abdomen), 46% (shoulder)
T_{max} (minutes)	70–100	IR: ~120; ER: 100%	IR: 60–120; ER: 6-10 hours	30–60	15–18 (hours); no characteristic peak observed
Protein binding	90%–96%	15%	40%	>99.9%	~90%
Metabolism	Hepatic via CYP3A4	Negligible (<10%)	Hepatic via CYP1A2	Auto-oxidation, glucuronidation, methylation, demethylation, and sulfation	Conjugation, dealkylation, sulfation, glucuronidation, and multiple CYP isoenzymes
Half-life (hours)	2–8	8–12	~6	0.8–3	~5–7
Elimination	Feces (~82%); urine (2%–6%)	Urine (90% unchanged)	Urine (<10% unchanged, 60% metabolites)	Urine	Urine (~71% inactive, <1% unchanged), feces (~23%)

5-HT, serotonin; NA, not applicable.

[a]Antagonist.

Dopamine agonists work by directly stimulating postsynaptic dopamine receptors within the striatum. The two families of dopamine receptors are D_1 and D_2. The D_1-like receptor family includes the D_1 and D_5 dopamine subtype receptors, and the D_2-like receptor family includes D_2, D_3, and D_4 dopamine subtype receptors. Stimulation of D_2 receptors is largely responsible for reducing rigidity and bradykinesia, whereas the precise role of the D_1 receptors remains uncertain.[37] Pramipexole and ropinirole exhibit selectivity for D_2 receptors without any significant affinity for D_1 receptors, whereas rotigotine has activity at all dopamine receptors.[38–40] Although the dopamine agonists differ slightly from each other in terms of their affinities for dopamine receptor subtypes, these agents produce similar clinical effects when used to treat PD, and no compelling

evidence favors one agent over another strictly on efficacy measures. Instead, experience with the nonergoline dopamine agonists, specifically pramipexole and ropinirole, makes them currently preferred as initial dopamine agonists. Thus, either agent would be acceptable as initial therapy in L.M. where drowsiness occurs at roughly the same incidence (ie, pramipexole 36% vs ropinirole 40%).

CASE 59-1, QUESTION 6: The decision is made to begin pramipexole in L.M. How effective is pramipexole compared to ropinirole in the initial treatment of PD?

Pramipexole

Pramipexole has been well studied as monotherapy in patients with early-stage PD and as an adjunct to levodopa therapy in advanced-stage disease.[38–40] These trials were multicenter, placebo-controlled, parallel-group studies, and parts of the Unified Parkinson's Disease Rating Scale (UPDRS) were used as the primary outcome measures, which includes improvement in ADLs (Part II) and motor function scores (Part III). Each evaluation on the UPDRS is rated on a scale of 0 (normal) to 4 (can barely perform). Lower scores on the UPDRS after treatment indicate an improvement in overall performance.

To view the UPDRS and other assessment tools for the symptoms of PD, visit http://www.movementdisorders.org/MDS/Education/Rating-Scales.htm.

The evidence for the efficacy of pramipexole in early PD comes from two large-scale, double-blind, placebo-controlled studies that included a total of 599 patients with early-stage PD (mean disease duration of 2 years).[39,40] In the first study, 264 patients were randomly assigned to receive one of four fixed doses (1.5, 3, 4.5, or 6 mg/day) or placebo.[39] The pramipexole-treated patients had a 20% reduction in their total UPDRS scores compared with baseline values, whereas no significant improvement was observed in the

placebo-treated patients. A trend toward decreased tolerability was noted because the pramipexole dosage was escalated especially in the 6 mg/day group. A second study of 335 patients titrated doses up to the maximal tolerated dose (not to exceed 4.5 mg/day) and then followed patients for a 6-month maintenance phase.[40] The mean pramipexole maintenance dosage was 3.8 mg/day. Those treated with pramipexole experienced significant improvements in both the ADL scores (22%–29%; $P < .0001$) and motor scores (25%–31%; $P < .0001$), whereas there were no significant changes in the placebo group.

Ropinirole

Similar to pramipexole, ropinirole is a synthetic nonergoline dopamine agonist. Although the drug is pharmacologically similar to pramipexole, it has some distinct pharmacokinetic properties (see Table 59-3). Unlike pramipexole, which is primarily eliminated by renal excretion, ropinirole is hepatically metabolized and undergoes significant first-pass hepatic metabolism.[41] Similar to pramipexole, ropinirole is approved for use as monotherapy in early-stage idiopathic PD and as an adjunct to levodopa therapy in patients with advanced-stage disease.

Ropinirole has not been directly compared with pramipexole in randomized, double-blind comparisons, but it appears to have comparable efficacy in indirect comparison. In several randomized, double-blind, multicenter, parallel-group studies, the efficacy and safety of ropinirole versus bromocriptine or levodopa after 6 months of treatment in patients with early PD were compared. Significant improvement was seen in UPDRS motor scores by ~20% to 30% when compared with baseline values for levodopa over ropinirole, but ropinirole was superior to bromocriptine.[42,43]

Rotigotine

Rotigotine is a nonergoline dopamine receptor agonist that is formulated in a transdermal patch delivery system designed for once-a-day application. It was voluntarily withdrawn from the U.S.

market in 2008 because of problems with crystal formation in the patches; however, the patch was reformulated and reapproved by the U.S. Food and Drug Administration (FDA) in April 2012. The original and reformulated patches have demonstrated efficacy as monotherapy in early-stage PD,[44–47] whereas only the original formulation has demonstrated efficacy as adjunctive therapy to levodopa in patients with advanced stages of PD.[48,49] It is, however, used in both situations.

A randomized, controlled trial conducted in Japanese patients with early-stage PD found that the mean improvement in UPDRS Part II and III sum scores was 8.4 in the rotigotine-treated group versus 4.1 in the placebo group (95% CI: –7.0 to –1.7*; P* = .002).[50] The average dose of rotigotine was 12.8 mg/24 hours in this study, which exceeds the highest recommended dose for early PD (6 mg/24 hours). A later 2016 study found similar results for improving motor control and ADLs.[51] Despite clear benefits in improving ADLs and motor function, there is insufficient evidence at this time to support that rotigotine prevents or delays motor fluctuations or dyskinesias.[21]

The transdermal delivery may have several advantages over traditional oral preparations, including possible increase in adherence, ease of use in patients with swallowing difficulty, and a more continuous stimulation of dopamine receptors. In theory, these benefits may translate into improved efficacy. In randomized, controlled trials comparing rotigotine to ropinirole as monotherapy or pramipexole as adjunct therapy, rotigotine has been found to be noninferior when typical clinical doses are used.[47,49]

Dosing

Case 59-1, Question 7: How are pramipexole and ropinirole dosed? What is the appropriate dose of pramipexole for L.M.?

Dopamine agonists should always be initiated at a low dosage and gradually titrated to the maximal effective dose, as tolerated. This approach minimizes adverse effects that may result in nonadherence

or discontinuation of the drug. In clinical trials, the maximal effective doses are variable and correlate with disease severity and tolerability. Studies have found no difference in efficacy or safety measures between immediate and long-acting formulations of dopamine agonists.[52] One fixed-dose study of pramipexole in early PD showed that most patients responded maximally at a dosage of 0.5 mg three times daily, although it has been shown to be effective and well tolerated in doses as high as 4.5 mg/day (divided).[38]

L.M. has normal renal function; therefore, immediate-release (IR) pramipexole should be started at an initial dosage of 0.125 mg three times daily for 5 to 7 days. His dosage may be increased weekly by 0.125 to 0.25 mg/dose as tolerated and up to the maximal effective dose, not to exceed the maximum dose of 4.5 mg/day.[38] Patients with a creatinine clearance of <50 mL/minute should be dosed less frequently than those with normal renal function.[38] Patients with a creatinine clearance of 30 to 50 mL/minute should receive a starting dose of 0.125 mg twice daily up to a maximal dose of 0.75 mg three times daily. Patients with a creatinine clearance of 15 to 30 mL/minute should receive a starting dose of 0.125 mg daily up to a maximal dose of 1.5 mg daily. Pramipexole has not been studied in patients with a creatinine clearance of <15 mL/minute or those receiving hemodialysis. A once-daily extended-release (ER) formulation of pramipexole is also available; patients can be switched overnight from IR pramipexole at the same daily dose. The use of the ER formulation is not recommended for patients with a creatinine clearance <30 mL/minute or for those receiving hemodialysis.

Ropinirole should be initiated at a dosage of 0.25 mg three times daily with gradual titration to clinical response in weekly increments of 0.25 mg/dose over the course of 4 to 6 weeks, not to exceed 24 mg/day.[41] Patients wishing to take the drug less frequently can be switched directly to an ER once-daily formulation, whereby the dose that is selected should most closely match the total daily dose of the IR formulation. No dose adjustments for ropinirole are necessary in patients with renal dysfunction and can be used in doses up to 18 mg/day in patients on hemodialysis.

Transdermal rotigotine is available in several patch strengths (see Table 59-2). For patients with early-stage PD, it is recommended to start rotigotine at 2 mg/24 hours with dose increases of 2 mg/24 hours that are adjusted no sooner than weekly based on clinical response and tolerability.[53] The maximum recommended dose in early PD is 6 mg/24 hours, whereas 8 mg/24 hours is recommended in advanced PD. Clinical trials have often used doses up to 16 mg/24 hours.[49,54] The time to reach steady-state plasma concentrations of rotigotine is ~2 to 3 days after initial patch application.[53] A multinational, open-label study demonstrated that patients with advanced PD taking pramipexole <2 mg/day or ropinirole <9 mg/day can be safely switched directly to rotigotine with no cross-titration.[55] Rotigotine is metabolized via conjugation and *N*-dealkylation, and the inactive conjugates are excreted in the urine. No adjustments are required for patients with hepatic or renal insufficiency.

Adverse effects

Case 59-1, Question 8: What are the adverse effects of pramipexole and ropinirole? How can these be managed?

Because pramipexole, ropinirole, and rotigotine are all approved for use as monotherapy in early-stage disease and as adjunctive therapy in advanced-stage disease, the adverse events of these agents have been evaluated as a function of disease stage. In studies of patients with early-stage disease, the most common side effects were nausea (28%–47%), application site reactions (39%, rotigotine only), dizziness (25%–40%), somnolence (22%–40%), insomnia (17%–19%), constipation (14%), asthenia (14%), hallucinations (9%), and leg edema (5%).[25,38–43,54,56] Administration with food may help to relieve nausea and/or vomiting. With continued use, many patients exhibit tolerance to the gastrointestinal side effects. CNS side effects were the most common reason for discontinuation of these agents with older patients, particularly susceptible to hallucinations and other CNS side effects. The

incidence of orthostatic hypotension was relatively low (1%–9%), and may, in part, reflect the exclusion of patients with underlying cardiovascular disease in several of the studies.

In advanced-stage disease, the most common adverse events of dopamine agonists were orthostatic hypotension (10%–54%), dyskinesias (26%–47%), application site reactions (46%, rotigotine only, dose-related), nausea (25%), insomnia (27%), hallucinations (11%–17%), somnolence (11%), and confusion (10%).[38,41,53,57] The most common reasons for discontinuing these agents are mental disturbances (eg, nightmares, confusion, hallucinations, insomnia), and orthostatic hypotension. Dyskinesias that are experienced when dopamine agonists are used in combination with levodopa in advanced-stage disease may require lowering the dose of levodopa or, in some cases, the dopamine agonist.

Sudden, excessive daytime somnolence, including while driving, has been reported with dopamine agonists and has resulted in accidents.[38,41,53,58] Affected patients did not always report warning signs before falling asleep and believed they were alert immediately before the event. Labeling for these drugs includes a warning that patients should be alerted to the possibility of falling asleep while engaged in daily activities. Patients should be advised to refrain from driving or other potentially dangerous activities until they have gained sufficient experience with the dopamine agonist to determine whether it will hinder their mental and motor performance. Caution should be advised when patients are taking other sedating medications or alcohol in combination with dopamine agonists. If excessive daytime somnolence does occur, patients should be advised to contact their health care practitioner.

Dopamine agonist therapy in patients with PD is associated with 2- to 3.5-fold increased odds of developing an impulse control disorder.[59] The frequency appears similar for both pramipexole and ropinirole, whereas it is less clear with rotigotine. In one study, a prevalence of 6.1% was noted for pathologic gambling in patients with PD compared with 0.25% for age- and sex-matched controls.[60] These cases may represent variations of a behavioral syndrome termed “dopamine dysregulation syndrome.”[61] Other features of the

syndrome have been reported, including punding (carrying out repetitive, purposeless motor acts), hypersexuality, walkabout (having the urge to walk great distances during on-times, often with no purpose or destination and abnormalities in time perception), compulsive buying, binge eating, drug hoarding, and social independence or isolation.[61] The syndrome appears to be more common among younger, male patients with early-onset PD as well as those having novelty-seeking personality traits, depressive symptoms, and current use of alcohol or tobacco.[59,62] Management of impulse control disorders can be challenging because it often requires modification of dopaminergic therapies, which must be carefully balanced with the accompanying risk of worsening motor function. Underlying depression, if present, should be treated and may improve impulse control. Nonpharmacologic measures (such as limiting access to money or the Internet) may be helpful. In some cases, antipsychotic drugs may be considered, but they must also be used carefully to avoid precipitating motor disability.[63]

Lastly, it should be noted that the abrupt discontinuation of dopamine agonists and levodopa may precipitate the development of a withdrawal syndrome similar to neuroleptic malignant syndrome (NMS). This NMS-like syndrome known as parkinsonism hyperreflexia syndrome can lead to symptoms of hyperthermia, muscle rigidity, hyperreflexia, mental status changes, autonomic instability (eg, tachycardia, tachypnea, and blood pressure fluctuations), and laboratory changes.[64] Patients that develop these symptoms should be restarted on therapy and gradually tapered off to reduce withdrawal symptoms. When gone untreated, withdrawal from dopamine agonist therapy may be fatal.[65]

Although L.M. is younger than age 65 years, he may be at increased risk for visual hallucinations and cognitive problems from dopamine agonist therapy. He should be monitored closely for occurrence or exacerbation of these side effects. He should also be evaluated for lightheadedness before initiation of pramipexole and counseled to report dizziness or unsteadiness because this may lead to falls. He should be reassured that if these effects are caused by pramipexole. They should subside with time and that he should not

drive or operate complex machinery until he can assess the effect of the drug on his mental status. L.M. should be counseled about the possibility of excessive and potentially unpredictable, daytime somnolence because pramipexole is introduced. L.M. does not appear to have a problem with excessive alcohol use; however, he and his family should be educated about his increased risk for impulse control disorders and advised to report any new, unusual, or uncharacteristic behaviors or increased use of alcohol.

MONOAMINE OXIDASE-B INHIBITORS

The MAO-B inhibitors are irreversible inhibitors of MAO-B, a major enzymatic pathway responsible for the metabolism of dopamine in the brain, and inhibition increases the amount of striatal dopamine.[66] The discovery that ingestion of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) causes rapid and irreversible parkinsonism, which led to the finding that neurotoxicity associated with MPTP is not directly caused by MPTP itself but rather the oxidized product, L-methyl-4-phenylpyridinium (MPP).[8] The conversion to MPP is a two-step process mediated in part by MAO-B. Inhibition of MAO-B can inhibit the oxidative conversion of dopamine to potentially reactive peroxides. This finding has led investigators to study whether inhibition of this enzyme is neuroprotective.

Selegiline

In animals, pretreatment with selegiline (also referred to as deprenyl) protects against neuronal damage after the administration of MPTP.[32] The Deprenyl and Tocopherol Antioxidative Therapy of Parkinsonism (DATATOP) study was designed to test the hypothesis that the combined use of selegiline and an antioxidant (α-tocopherol) early in the course of the disease may slow disease progression.[67] The primary outcome was the length of time that patients could be sustained without levodopa therapy (an indication of disease progression). Early treatment with selegiline 10 mg/day delayed the need to start levodopa therapy by ~9 months compared with patients

given placebo; however, long-term observation showed that the benefits of selegiline were not sustained and diminished with time. In an extension of the study, patients originally assigned to selegiline tended to reach the endpoint of disability after 1 year of observation even more quickly than did those not assigned to receive selegiline.[68] Initial selegiline treatment did not alter the development of levodopa's adverse effects such as dyskinesias and wearing-off and on–off phenomena.

Although selegiline did not prove to be neuroprotective, the finding that MAO-B inhibitors can delay the need for dopaminergic therapy by at least several months is clinically relevant and is supported by several randomized, controlled trials.[69,70] Aside from the DATATOP trial, studies of selegiline are limited by relatively small sample sizes. As a result, a large meta-analysis of MAO-B inhibitors in early PD was conducted.[34] When analyzed for selegiline, the levodopa dose necessary to control symptoms was 67 mg (14–119 mg; P = .01) lower in the selegiline arm. This analysis found that the total, motor, and ADL scores of the UPDRS were significantly improved in the selegiline arm at 3 months. A subsequent Cochrane Review found that the selegiline-treated arms scored 3.79 points better (95% CI: 2.21, 5.3) when looking at the weighted mean difference in motor UPDRS score.[32] Although oral selegiline continues to be FDA-approved only as an adjunct treatment to carbidopa/levodopa, the evidence suggests efficacy in monotherapy and is used as monotherapy in practice.

Rasagiline

Rasagiline is a second-generation, irreversible selective inhibitor of MAO-B that is FDA-approved as both monotherapy and adjunct therapy in PD. Rasagiline is otherwise differentiated from selegiline primarily in that it is a more potent inhibitor of MAO-B and does not carry the same potential for adverse effects resulting from metabolites.[71] Like selegiline, rasagiline has also been found to protect from MPTP-induced parkinsonism in animal models.[32]

Rasagiline was studied as monotherapy in early PD in a randomized, double-blind, placebo-controlled trial comparing rasagiline 1 or 2 mg daily with placebo (N = 404).[72] After 6 months of therapy, the mean adjusted change in UPDRS scores compared with placebo was improved in both the 1- and 2-mg groups (P < .001).[72] These changes are quantitatively similar to those observed with levodopa therapy. This study used a delayed-start design, wherein at the end of the initial 6 months of treatment, patients who received placebo were then switched over to receive active treatment with rasagiline. For the rasagiline-treated patients, they continued on therapy. After an additional 6 months of study, it was found that patients receiving rasagiline for all 12 months had less functional decline than patients in whom rasagiline was delayed.[73] The mean adjusted difference in total UPDRS scores at 12 months for patients receiving rasagiline 2 mg/day for all 12 months was −2.29 compared with the delayed-start rasagiline 2-mg group (P = .01). As a result, rasagiline was FDA-approved for use as monotherapy in early PD. These encouraging findings also suggested that neuroprotection might be afforded by rasagiline and prompted a larger, more definitive study.

The Attenuation of Disease Progression with Azilect given once-daily (ADIAGO) study was also a randomized, placebo-controlled trial using the delayed-start methodology but with a much larger sample size (N = 1176).[74] Patients were randomly assigned to receive rasagiline or placebo for 36 weeks, at which time rasagiline-treated subjects continued therapy, and the placebo group was switched to rasagiline. All these patients were then followed for an additional 36 weeks. To prove disease modification attributable to rasagiline with either dose, the early-start treatment group had to meet each of three hierarchic endpoints, which was based on the magnitude and rate of change of UPDRS scores during different periods of the study. At the end of the study, rasagiline failed to meet all of the prespecified endpoints, and the authors were unable to confirm any disease-modifying effects.[74]

There are no head-to-head randomized controlled trials comparing rasagiline versus selegiline. Multiple meta-analysis and smaller

studies have compared both medications, but little difference between motor symptom control and time to levodopa therapy were seen.[75–77] Existing data were compared in an industry-sponsored, indirect meta-analysis, which found a significant advantage for rasagiline monotherapy on UPDRS scores.[78] Additionally, risk for discontinuation and adverse events favored rasagiline. Rasagiline is primarily metabolized via cytochrome P450 (CYP) 1A2 and *N*-dealkylation, whereas selegiline is metabolized via CYP2B6, CYP2C9, and CYP3A4/5 to amphetamine-like metabolites (L-methamphetamine and L-amphetamine). As a result of their MAO-B inhibition, similar precautions regarding drug interactions exist. Caution should be taken when using MAO-B inhibitors with proserotonergic agents such as antidepressants, triptans, and linezolid because of the risk of serotonin syndrome. Although tyramine-challenge studies have not demonstrated any clinically significant reactions with these MAO-B inhibitors, the product labeling still contains a warning that patients should be advised to restrict tyramine intake.[79,80]

Dosing

Selegiline is available in a 5-mg capsule or tablet and as a 1.25-mg orally disintegrating tablet. It is also available in a transdermal patch, but this formulation is not approved for use in PD (approved for the treatment of major depressive disorder). The bioavailability of conventional selegiline is low, and it undergoes extensive hepatic first-pass metabolism into amphetamine-based metabolites, which may contribute to neurologic side effects.[66] The usual dosage of conventional selegiline is 10 mg/day administered as 5 mg in the morning and early afternoon. It is not given in the evening because excess stimulation from metabolites (L-methamphetamine and L-amphetamine) can cause insomnia and other psychiatric side effects.[81] The orally disintegrating tablet formulation dissolves in the mouth in contact with saliva and undergoes pregastric absorption. This formulation minimizes the effect of first-pass metabolism in comparison with conventional selegiline, which results in higher

plasma concentrations and reductions in the amphetamine-based metabolites.[66] Selegiline should be used with caution in patients with severe hepatic impairment or with creatinine clearance <30 mL/minute.

Rasagiline is available in 0.5- and 1-mg tablets. When used as monotherapy, it is initiated at 1 mg daily. When combined with levodopa, the initial dose is lowered to 0.5 mg daily and can be increased to 1 mg daily based on response. In patients with mild hepatic impairment, the dose should be reduced to 0.5 mg daily, but use should be avoided in those with moderate-to-severe hepatic impairment. Additionally, because rasagiline lacks the amphetamine-like metabolites of selegiline, it also lacks the time-specific dosing constraints.

Adverse effects

The most common adverse effects of both agents include nausea (6%–20%), dizziness (11%–14%), headache (4%–14%), and dry mouth (4%–6%).[66,80,81] CNS effects such as hallucinations, vivid dreams, and confusion also occur but at a lower rate as compared with dopamine agonists. Although the oral disintegrating tablet reduces the amphetamine-based metabolites, there are higher rates of reported side effects likely as a result of the higher plasma concentration of selegiline.[66] A large meta-analysis of MAO-B inhibitors in early PD found a higher incidence of reported side effects among the MAO-B inhibitor (all but one study used selegiline) versus non-MAO-B inhibitor groups (OR: 1.36, 1.02–1.8, P = .04).[34] However, these agents are generally considered well tolerated.[80]

LEVODOPA

Case 59-1, Question 9: L.M. initially responded well to pramipexole 1 mg three times daily for 18 months with increased ability to paint and carry out ADLs. During the past few weeks, he has noticed a gradual worsening in motor symptoms without improvement in insomnia and once again is having difficulty holding a paintbrush, getting out of a chair, and his posture is slightly more stooped. He also notes feeling tired throughout much of the day. The

neurologist wants to start levodopa at this time for his PD symptoms. What should be considered before starting levodopa?

Dopamine itself does not cross the blood–brain barrier. Levodopa, a dopamine precursor with no known pharmacologic action of its own, crosses the blood–brain barrier, where it is converted by the enzyme aromatic amino acid (dopa) decarboxylase to dopamine. Levodopa has been a mainstay of PD treatment since the 1960s. Nearly all patients will eventually require treatment with the drug regardless of their initial therapy.

Because significant amounts of levodopa are peripherally (extracerebrally) metabolized to dopamine by dopa decarboxylase, extremely high doses are necessary if administered alone. For this reason, levodopa is always coadministered with a dopa decarboxylase inhibitor. This allows the dose of levodopa to be decreased by 75%.[82] By combining levodopa with a dopa decarboxylase inhibitor that does not penetrate the blood–brain barrier, a decrease in the peripheral conversion of levodopa to dopamine can be achieved, whereas the desired conversion within the striatum remains unaffected. This combination also shortens the time needed to achieve optimal effects by several weeks because the dopa decarboxylase inhibitor substantially decreases dose-limiting levodopa-induced nausea and vomiting. The two peripheral decarboxylase inhibitors in clinical use are benserazide (unavailable in the United States) and carbidopa. A fixed combination of carbidopa and levodopa is available in ratios of 1:4 (carbidopa/levodopa 25/100) and 1:10 (carbidopa/levodopa 10/100 and 25/250). Carbidopa/levodopa is also available as an IR, orally disintegrating tablet, and ER capsule, which both may be used in early PD. In addition, controlled-release (CR), ER, and intestinal gel formulations are available and are discussed for management of motor complications.

In the case of L.M., he is now experiencing bothersome symptoms despite near-maximal dopamine agonist therapy without improvement in sleep besides. Moreover, his bothersome symptoms have progressed sufficiently to threaten his livelihood. Although the

dose of pramipexole could be increased, he may experience more daytime somnolence; thus, levodopa should be added to his regimen.

Dosing

Case 59-1, Question 10: The decision is made to begin L.M. on carbidopa/levodopa. How should it be dosed?

About 70 to 100 mg/day of carbidopa is necessary to saturate peripheral dopa decarboxylase.[82] It is usually unnecessary and more costly to administer carbidopa in higher amounts. Therapy should be initiated with IR carbidopa/levodopa 25 mg/100 mg three times a day. The IR formulation is preferred because it allows for much easier dose adjustment. In the case of L.M., the dose can then be increased by 100 mg of levodopa every day or every other day up to eight tablets (800 mg), up to the maximal effective dose, to individual requirements, or as tolerated.

Troublesome peak-dose dyskinesias may occur because of high levels of dopaminergic drug activity. If these occur, the dose or frequency may be adjusted while giving consideration to balancing the most useful dose (eg, maximizing the patient's on-time) with that which does not produce unacceptable side effects (eg, troublesome dyskinesias). Because L.M. is currently being treated with a dopamine agonist, he must be monitored closely for the development of motor complications with the addition of levodopa.

Most patients with early PD will begin therapy on levodopa 300 mg/day and will demonstrate response before reaching 1000 mg/day.[14,82] When levodopa doses exceed 750 mg/day, patients such as L.M. can be switched from the 1:4 ratio of carbidopa/levodopa to the 1:10 ratio to prevent providing excessive amounts of decarboxylase inhibitor. For example, if L.M. needed 800 mg/day of levodopa, two carbidopa/levodopa 10/100 tablets four times daily could be administered. If L.M. had not been initially treated with a dopamine agonist, some clinicians would consider

adding a dopamine agonist after the daily levodopa dose has been increased to >600 mg because dopamine agonists directly stimulate dopamine receptors, have longer half-lives, and result in a lower incidence of dyskinesias, which provides a smoother dopaminergic response.

Clinical response to levodopa therapy may be altered by modifying dietary amino acid ingestion.[82] Levodopa is actively transported across the blood–brain barrier by a large neutral amino acid transport system. This transport system also facilitates the blood-to-brain transport of amino acids such as L-leucine, L-isoleucine, L-valine, and L-phenylalanine. Levodopa and these neutral amino acids compete for transport mechanisms, and high plasma concentrations of these amino acids can decrease brain concentrations of levodopa.[83] Patients should be instructed to take IR carbidopa/levodopa 30 minutes before or 60 minutes after meals for optimal efficacy. If nausea develops and administration with food is considered, a low-protein meal should be encouraged.

Adverse effects

Case 59-1, Question 11: Since initiating carbidopa/levodopa, L.M. reports feeling restless and agitated at times, but these symptoms do not impact his sleep. He further discloses that his sleep has seemingly improved to about 7 hours per night. Could levodopa be contributing to these problems? If so, how should this be managed?

Although levodopa is the most effective agent for PD, it is associated with many undesirable side effects such as nausea, vomiting, and anorexia (50% of patients); postural hypotension (30% of patients); and cardiac arrhythmias (10% of patients).[14] In addition, mental disturbances are encountered in 15% of patients, and abnormal involuntary movements (dyskinesias) can be seen in up to 55% of patients during the first 6 months of levodopa treatment.[83]

Although more commonly encountered with dopamine agonists, psychiatric side effects are also associated with levodopa therapy

and include confusion, depression, psychosis, hypomania, vivid dreams, and insomnia (1%–9% of patients).[82] Those with underlying or preexisting psychiatric disorders and those receiving high doses of levodopa for prolonged periods are at the greatest risk.[84] Concurrent anticholinergics or amantadine therapy can exacerbate these symptoms. Advancement of the PD itself correlates with cognitive decline and greater frequency of CNS findings, possibly mediated through an underlying Lewy body pathology.[20] In some situations, it may be difficult to separate the respective drug from disease effects.

Some patients receiving levodopa experience psychomotor excitation (eg, overactivity, restlessness, agitation). Similarly, hypomania has been reported in up to 8% of patients and is characterized by grandiose thinking, flight of ideas, tangential thinking, and poor social judgment. Normal sexual activity often is restored with improved motor function; however, hypersexuality and libido are increased in about 1% of levodopa-treated patients.[85]

In general, most of the mental disturbances are dose-related and can be lessened by reducing the dose of the dopaminergic agent. In patients such as L.M. who are concurrently receiving levodopa and a dopamine agonist, the dose reduction should be attempted first with the dopamine agonist. If symptoms do not improve, a reduction in the dose of levodopa may also be warranted. These dose reductions may, however, be impractical for L.M. because a return of parkinsonian symptoms is likely, and the benefits of levodopa therapy may outweigh the risk for mental disturbances.

ANTICHOLINERGICS

Case 59-1, Question 12: What role do anticholinergic drugs play in the treatment of PD? Should L.M. receive an anticholinergic agent?

Anticholinergic drugs have been used to treat PD since the mid-1800s, when it was discovered that symptoms were reduced by the belladonna derivative hyoscine (scopolamine).[20] Currently, they are

used to specifically target tremor. Although tremor may improve with dopaminergic drugs via the restoration of balance between dopamine and acetylcholine, resolution of tremor may be incomplete. Anticholinergic drugs such as benztropine and trihexyphenidyl work by blocking the excitatory neurotransmitter acetylcholine in the striatum, which minimizes the effect of the relative increase in cholinergic sensitivity. Until the late 1960s, when amantadine and levodopa were introduced, anticholinergics were a mainstay of treatment; however, because of their undesirable side effect profile and poor efficacy relative to levodopa in treating bradykinesia and rigidity, anticholinergic agents are no longer used as first-line agents. These drugs produce both peripherally and centrally mediated adverse effects. Peripheral effects, such as dry mouth, blurred vision, constipation, and urinary retention, are common and bothersome.[24] Anticholinergic agents can increase intraocular pressure and should be avoided in patients with angle-closure glaucoma. CNS effects can include confusion, impairment of recent memory, hallucinations, and delusions.[20,24] Patients with PD are often more susceptible to these central effects because of advanced age, intercurrent illnesses, and impaired cognition.[24] Anticholinergics are usually reserved for the treatment of resting tremor early in the disease, particularly in younger patients with preserved cognitive function. Given his history and clinical presentation and based on the absence of tremor, L.M. would not be an appropriate candidate for an anticholinergic drug.

Treatment through the Progression of Parkinson Disease

LEVODOPA AND ADJUNCTIVE THERAPY

The chronic, progressive nature of PD predicts that patients will develop worsening of motor control through the later stages of the disease; thus, enhanced motor control through the use of levodopa, in conjunction with symptomatic adjunctive agents, will be necessary. Agent selection is guided by efficacy for motor symptom control,

adverse effects, and motor complication risk. Agents indicated by the AAN,[19] EFNS/MDS-ES,[21] NICE,[20] and Canadian[22] guidelines for symptomatic adjunct therapy and management of motor complications in late PD are outlined in **Figure 59-2**.

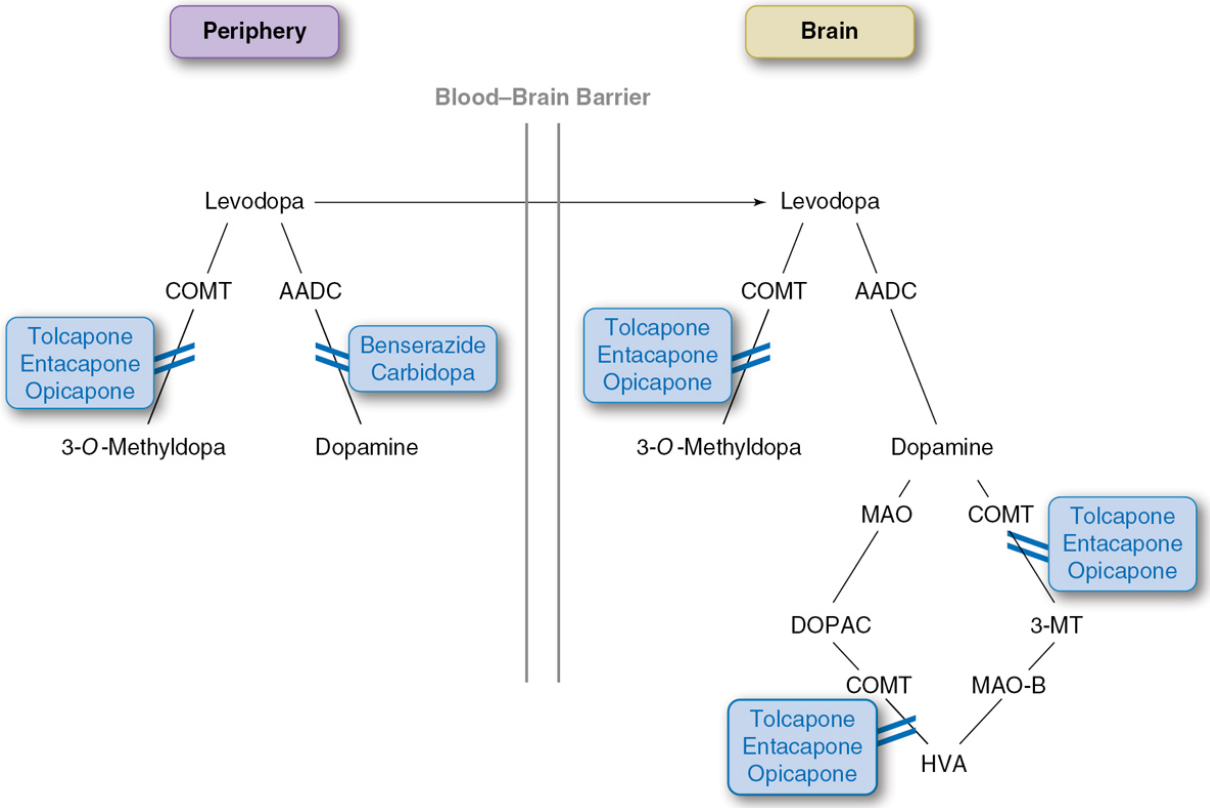

Figure 59-2 Levodopa metabolism in the human body. AADC, aromatic amino acid decarboxylase; COMT, catechol-*O*-methyltransferase; DOPAC, 3,4-dihydroxyphenylacetic acid; HVA, homovanillic acid; MAO, monoamine oxidase; 3-MT, 3-methoxytyramine.

MOTOR COMPLICATIONS

CASE 59-1, QUESTION 13: After 3 years of levodopa therapy, L.M. began to experience immobility in the mornings. Nearly every day, he has periods in which he cannot move followed by a sudden switch to a fluid-like state, which is often associated with dyskinetic activity. He continues to take carbidopa/levodopa three times daily but gains symptomatic relief for only 3 to 4 hours after a dose. Also, the response to a given dose varies and is often less

in the afternoon. At times, he becomes “frozen,” particularly when he needs to board an elevator or is required to move quickly. What are possible explanations for these alterations in clinical response?

Although variable, the initial levodopa response period may last up to 5 years. After this initial period of stability, 50% to 90% of patients receiving levodopa for 5 or more years will eventually experience motor complications.[86] Motor complications may present as periods of too much (dyskinetic) dopaminergic activity, too little (akinetic) dopaminergic activity, or in combination.

In evaluating these motor fluctuations, it is important to ascertain which effects are attributable to the disease and which are attributable to the drug. For example, levodopa-induced peak-dose dyskinesias often appear concurrently with the development of motor fluctuations.[86,87] Peak-dose dyskinesias consisting of choreiform with brief, irregular, and jerky movements are the most common form of dyskinesias that occur with chronic levodopa (and sometimes dopamine agonist) therapy. These symptoms frequently subside at the end of the dosing interval because levodopa levels fall. Their severity is related to levodopa dose, disease duration and stage, and younger age at onset.[87] If peak-dose dyskinesias occur, the following strategies should be considered: levodopa dose can be lowered, but given more frequently; consideration can be given to switching patients to IR tablets if taking modified-release formulations of carbidopa/levodopa (for ease in refining dose adjustments); agents that prolong the half-life of levodopa, but do not provide stable levodopa plasma concentrations (eg, COMT inhibitor, MAO-B inhibitor) can be added, or an antidyskinetic agent such as amantadine can be used. Variations in the rate and extent of levodopa absorption, dietary substrates (eg, large neutral amino acids) that compete with cerebral transport mechanisms, levodopa drug–drug interactions (**Table 59-4**), and competition for receptor binding by levodopa metabolites can further explain the variable responses observed to levodopa.

Table 59-4
Levodopa Drug Interactions

Drug	Interaction	Mechanism	Comments
Anticholinergics	↓ Levodopa effect	↓ Gastric emptying, thus ↑ degradation of levodopa in gut, and ↓ amount absorbed	Watch for ↓ levodopa effect when anticholinergics cause ↓ GI motility. When anticholinergic therapy is discontinued in a patient on levodopa, watch for signs of levodopa toxicity. Theoretic interaction with minor clinical significance
Ferrous sulfate	↓ Levodopa oral absorption by 50%	Formation of chelation complex	Avoid concomitant administration or separate administration by at least 2 hours.
Food	↓ Levodopa effect	Large, neutral amino acids compete with levodopa for intestinal absorption	Although levodopa is usually taken with meals to slow absorption and ↓ central emetic effect, high-protein diets should be avoided.
MAOI (eg, phenelzine, tranylcypromine)	Hypertensive crisis	Peripheral dopamine and norepinephrine	Avoid combination use; monoamine oxidase type B (MAO-B) inhibitors such as selegiline can be used, but the dose of levodopa should be reduced after 2–3 days of therapy; carbidopa might minimize hypertensive reaction to levodopa in patients receiving an MAOI.
Methyldopa	↑ or ↓ levodopa effect	Acts as central and peripheral decarboxylase inhibitor	Observe for response; may need to switch to another antihypertensive.
Metoclopramide	↓ Levodopa effect	Central dopamine blockade	Avoid combination use.
Neuroleptics (eg, butyrophenones, phenothiazines)	↓ Levodopa effect	Central blockade of dopamine neurotransmission	Avoid combination use; important interaction.
Phenytoin	↓ Levodopa effect	Mechanism unknown	Avoid combination use.
Pyridoxine (vitamin B_6)	↓ Levodopa effect	Peripheral decarboxylation of levodopa	Not observed when levodopa given with carbidopa; avoid levodopa monotherapy with vitamin B_6 supplementation.
Tricyclic antidepressants	↓ Levodopa effect	Levodopa degradation in gut because of delayed emptying	Use with caution.

GI, gastrointestinal; MAOI, monoamine oxidase inhibitor.

Two of the more common motor complications are the wearing-off effect and the on–off effect. The wearing-off effect is most predictable, which occurs in the latter part of the dosing interval after a period of relief. Because levodopa is a short-acting agent with an elimination half-life of about 1.5 hours, much of the effect from the evening dose will dissipate by morning.[82,86] For this reason, it is not surprising that L.M. is experiencing a period of immobility on arising. This symptom is alleviated in most patients shortly after taking the morning dose. Wearing-off can be improved by various means such as shortening the dosing interval or with the addition of adjunctive therapy (if not already present) with a dopamine agonist, MAO-B inhibitor, or levodopa extender such as a COMT inhibitor. The on–off effect is described as random fluctuations from mobility (often associated with dyskinesias) to the parkinsonian state, which

appears suddenly as if a switch has been turned on or off. These fluctuations can last from minutes to hours and increase in frequency and intensity with time. Despite accompanying dyskinesias, most patients prefer to be in an on rather than an off (or akinetic) state; however, for some patients, dyskinesias can be more disabling than parkinsonism.

Early in the course of disease, it is usually possible to control parkinsonian symptoms without inducing dyskinesias via medication adjustments; however, because the disease advances and the therapeutic window narrows, cycling between on-periods complicated by dyskinesia and off-periods with resulting immobility is common.[86,87] Eventually, despite adjustments in levodopa dose, many patients with advanced PD experience either mobility with severe dyskinesias or complete immobility. In most patients, this effect has no clear relationship to the timing of the dose or levodopa serum levels.[86]

The pathophysiologic basis for motor complications and dyskinesias is not entirely clear, but incomplete delivery of dopamine to central receptors is likely responsible.[86] Because the disease progresses and dopamine terminals are lost, the capacity to store dopamine presynaptically is diminished, whereby the ability to maintain relatively constant striatal dopamine concentrations is impaired.[86] As a consequence, dopamine receptors are subject to intermittent and pulsatile stimulation rather than a more physiologic tonic stimulation. Overactivity of excitatory pathways mediated by neurotransmitters such as glutamate may also be involved.[86]

CASE 59-1, QUESTION 14: What options are available to reduce the motor fluctuations experienced by L.M.?

MODIFIED-RELEASE CARBIDOPA/LEVODOPA FORMULATIONS

A more sustained delivery of levodopa than that achieved with routine oral dosing may theoretically reduce motor complications by more effectively replicating normal physiology. Three products designed to prolong carbidopa/levodopa delivery include a CR tablet,

an ER capsule, and an enteral suspension administered as a gastrointestinal infusion. The use of the enteral suspension for gastrointestinal infusion has shown reductions in off-time of 1.91 hours (P = .0018) and an increase in on-time of 1.86 hours (P = .0059) in a 12-week study of patients with severe motor fluctuations and hyper/dyskinesias.[88] As a result of its pump administration via a permanent duodenal/upper jejunal tube, this method is typically reserved as last-line therapy for use in specialized centers.

Controlled-release carbidopa/levodopa

A CR tablet formulation of carbidopa/levodopa is available, which contains 25-mg carbidopa and 100-mg levodopa or 50-mg carbidopa and 200-mg levodopa in an erodible polymer matrix that retards gastric dissolution. Although off-time should theoretically be reduced by the slower rate of plasma levodopa decline, clinical study has generally not found a sustained difference in off-time or a reduction in dyskinesias with the CR preparation compared with the IR preparation.[20,21] As a result, switching to CR carbidopa/levodopa as a primary strategy to reduce off-time or lessen dyskinesias is not recommended.[20]

A likely reason for the lack of superior effect with CR carbidopa/levodopa as compared with the IR formulation is its variable absorption. CR carbidopa/levodopa is about 30% less bioavailable than the IR formulation. Patients converted from standard carbidopa/levodopa to the CR formulation should receive a dose that will provide 10% more levodopa, and then the dose should be titrated upward to clinical response.[89] Interestingly, administration with food enhances levodopa's peak by 25%. Given that there is no obvious advantage to CR carbidopa/levodopa, L.M. should not be switched to this formulation.

Extended-release carbidopa/levodopa

The ER capsule formulation of carbidopa/levodopa contains a combination of both immediate- and ER beads designed to circumvent the pharmacokinetic concerns seen with the CR tablet

formulation. Although both formulations persist for up to 6 hours, the ER capsule provides a faster time to symptom relief, with a peak that is comparable to the IR formulation (1 hour vs up to 2 hours for CR).[90] Similar to CR, the ER formulation reduces levodopa bioavailability by ~50%.[91] As such, the manufacturer provides specific dose conversions from IR preparations. Converse to the CR preparation, high-fat and high-calorie food reduces levodopa peak and may delay absorption by 2 to 3 hours, and it is recommended that the first dose of the day be given 1 to 2 hours prior to eating. In patients with difficulty swallowing, these capsules may be opened and sprinkled on applesauce, which is an additional advantage to the CR formulation.

The ability of the ER formulation to reduce off-time was evaluated in a placebo-controlled study randomizing 393 patients to immediate or ER formulations over 22 weeks.[92] After being titrated to a stable dose during weeks 1 to 9, patients were followed for an additional 13 weeks. Compared to baseline evaluations, ER patients had a reduction in off-time by ~1 hour/day ($P < .0001$) when compared to the IR formulation. This effect was accompanied by an increase in on-time without troubling dyskinesia of ~1 hour ($P = .0002$). Notably, of patients converted per manufacturer direction, 60% of patients required a further dosage increase and 13% required a dosage decrease.[92]

Based upon this evidence, the ER formulation may improve off-time for L.M. but is unlikely to impact his dyskinesias. Therefore, it may not be appropriate to switch therapy. Taking his IR carbidopa/levodopa more frequently while avoiding substantial increases in the total daily dose, which could worsen his dyskinesias, may improve his condition. Taking his morning dose before arising from bed may help with his early-morning problems. If the symptoms that L.M. is experiencing are not improved with these changes, a number of adjunctive agents such as dopamine agonists, apomorphine rescue, amantadine, COMT inhibitors, and MAO-B inhibitors can be considered.

Inhaled levodopa

The inhaled version of levodopa (Inbrija®) was FDA-approved in 2018 for use as an on-demand rescue therapy during wearing-off periods of carbidopa/levodopa therapy.[93] Patients can introduce an additional 42 to 84 mg of levodopa up to five times daily with a maximum dose of 420 mg/day. In a randomized study, inhaled levodopa improved symptoms with a mean difference of 3.9 points on the UPDRS scale versus placebo at 30 minutes as well as leading to more patients having and maintaining an "on" response at 60 minutes (57% vs 36%).[94] Compared to apomorphine for rescue therapy, inhaled levodopa has a significantly smaller magnitude of difference in UPDRS and longer time to onset around 30 minutes. This finding may be concerning where the effects may not translate into a clinically meaningful response for some patients. In studies, a patient's time in the "off" state was not reduced in the levodopa group, which may also indicate that therapy is not adequate. Common side effects with inhaled levodopa compared with placebo in trials included cough (15% vs 2%), upper respiratory tract infection, nausea, and discolored sputum. The rate of dyskinesia was low.

DOPAMINE AGONISTS

The effectiveness of pramipexole added to levodopa therapy in advanced PD was evaluated in a multicenter, placebo-controlled study of 360 patients with a mean disease duration of 9 years.[95] Pramipexole was titrated gradually to the maximal effective dose as tolerated. At the end of a 6-month maintenance period, patients treated with pramipexole had a 22% improvement in their ADLs ($P < .0001$) and a 25% improvement in their motor scores ($P < .01$) compared with baseline values. Patients treated with pramipexole also had a 31% improvement in the mean off-time compared with a 7% improvement in the placebo-treated group ($P < .0006$). Dyskinesias and hallucinations were more common in pramipexole-treated patients and necessitated levodopa dose reduction in 76% of patients compared with 54% in the placebo group. The total daily

levodopa dose was decreased by 27% in those treated with pramipexole compared with 5% in the placebo group.

Ropinirole has been found to improve motor scores when added to levodopa therapy in patients with advanced-stage disease.[52] In a multicenter, double-blind, randomized parallel-group study, patients treated with ropinirole achieved a greater reduction in the percentage of time spent off during waking hours when compared to placebo (11.7% vs 5.1%), which was a difference of 0.4 hours. A greater number of ropinirole-treated patients achieved a significant 20% reduction in time spent off (35% vs 13%, $P = .003$). In those treated with levodopa, the levodopa dose was decreased by an average of 19%.

Long-acting dopamine agonist formulations, including ER ropinirole and rotigotine, have also shown reductions in off-time. In a study of 208 patients with PD not optimally controlled with levodopa after up to 3 years of therapy with <600 mg/day of levodopa, a prolonged-release, once-daily formulation of ropinirole was found to improve motor scores in a similar fashion to increase the levodopa dose; however, only 3% of ropinirole-treated subjects experienced dyskinesias compared with 17% of levodopa-treated patients ($P < .001$).[96] In moderate-to-advanced PD, treatment benefits were observed within 2 weeks of initiation.[97] ER ropinirole has been found to reduce off-time more than the IR preparation in advanced PD. A randomized, double-blind trial of 343 patients over 24 weeks found that compared to the IR formulation, significantly more patients given the ER formulation maintained at least a 20% reduction in off-time (adjusted OR: 1.82, 1.16–2.86, $P = .009$).[98] These results are confounded by the relatively higher doses of ER ropinirole and greater reductions in levodopa achieved by the ER formulation. Rotigotine has also been evaluated for reduction in off-time in patients with advanced PD and has been shown to significantly reduce off-time by ~2.5 hours, with benefits seen as early as the first week of therapy.[53]

Because L.M. has advanced disease and is experiencing motor fluctuations despite a treatment regimen that includes a dopamine agonist whereby further dose adjustments of the dopamine agonist

may provide little additional benefit. Any adjustments must be made with consideration of worsening his dyskinesias and the possibility of exacerbating CNS adverse effects.

Apomorphine

Apomorphine is a dopamine agonist that is approved as rescue therapy for the treatment of hypomobility or "off" episodes in patients with PD. In a randomized, double-blind, parallel-group study of 29 patients, rescue treatment with injectable apomorphine resulted in a 34% reduction in off-time, ~2 hours, compared with 0% in the placebo group (P = .02).[99] Mean UPDRS motor scores were reduced by 23.9 points (62%) in those treated with apomorphine when compared with 0.1 (1%) in those receiving placebo (P < .001). Adverse events in the apomorphine group included yawning (40%), dyskinesias (35%), drowsiness or somnolence (35%), nausea or vomiting (30%), and dizziness (20%), although only yawning was statistically different from placebo (40% vs 0%; P = .03). Additionally, a randomized, double-blind, placebo-controlled, parallel-group study compared the mean change from predose to 30 minutes postdose in the MDS-UPDRS III at 12 weeks during the maintenance phase with sublingual apomorphine for acute, intermittent treatment of "off" episodes. Apomorphine showed a least-square mean improvement of −11.1 points (95% CI: −14.0, −8.2), versus −3.5 points for the placebo group (95% CI: −6.1, −0.9). Adverse events were similar to those seen in previous studies of apomorphine except for an increase in oropharyngeal-related events reported in 31% of patients taking the sublingual formulation.[100]

Because nausea and vomiting frequently occur with both sublingual and injectable apomorphine treatment, it should be administered with an antiemetic such as trimethobenzamide. The antiemetic should be started 3 days before initiating apomorphine and continued for the first 2 months of treatment.[99,101] Apomorphine should not be used with ondansetron and other serotonin antagonists used to treat nausea because the combination may cause severe hypotension. In addition, other antiemetics, such as

prochlorperazine and metoclopramide, should not be given concurrently because these dopamine antagonists may decrease the effectiveness of apomorphine.

Doses of sublingual apomorphine range from 10 to 30 mg as needed for intermittent treatment of “off” episodes with a maximum of five doses in one day. Doses of injectable apomorphine range from 2 to 6 mg per subcutaneous injection.[99] A 2-mg test dose is recommended prior to injectable apomorphine while monitoring blood pressure. If tolerated, the recommendation is to start with a dose of 2 mg and increase the dose by 1 mg every few days if needed. Peak plasma levels are observed within 10 to 60 minutes after dosing, so the onset of therapeutic effect is rapid. The test dose and titration are time-consuming and must be done under physician supervision, and patients may require someone else to inject the drug once hypomobility has occurred. In severe cases, subcutaneous infusions have been used, but are limited to research settings and high-level clinical centers. For these reasons, apomorphine is not widely used. Given that L.M. is experiencing motor fluctuations almost daily, long-term frequent apomorphine use would not be a viable solution in his situation.

AMANTADINE

The antiviral agent, amantadine, was serendipitously found to improve PD symptoms when a patient given the drug for influenza experienced a remission in her parkinsonism.[101] Amantadine reduces all the symptoms of parkinsonian disability in about 50% of patients usually within days after starting therapy; however, early trials indicated that amantadine efficacy might be limited by the development of tachyphylaxis within 1 to 3 months.[102] Although the trials suggested reductions in dyskinesias by up to 40%, previous evaluations of amantadine for the reduction of dyskinesias have been limited by methodological concerns.

The pathophysiologic basis for the efficacy of amantadine in PD is not entirely understood. It may augment dopamine release and possibly inhibit its reuptake.[103] Anticholinergic action has also been

suggested. Excess glutamatergic activity has been implicated in the pathophysiology of dopaminergic dyskinesias. Amantadine has been found to be an antagonist at *N*-methyl-D-aspartate (NMDA) receptors and to block glutamate transmission[100] and has consistently shown ~50% reductions in dyskinesia severity and duration without adversely impacting motor performance.[104–117] Two trials have evaluated long-term efficacy of amantadine in patients with levodopa-induced dyskinesia after treatment for 6 months to 1 year. These trials assessed for change in UPDRS motor examination and motor complication subscores with amantadine washout over 3 weeks to 3 months. Those discontinuing amantadine had deterioration in levodopa-induced dyskinesia compared to the continuing group within a median time of 7 days suggesting the possibility of continued benefit despite the tachyphylaxis suggested in earlier trials.[108,109] Guidance suggests reserving consideration for amantadine use to those in whom dyskinesia is not adequately managed on other therapies.[20]

The decision to use amantadine in L.M. should be based on whether his dyskinesias are deemed more problematic than his duration of off-time. If so, amantadine should be started at 100 mg/day taken at breakfast; an additional 100-mg dose can be taken with lunch 5 to 7 days after initiation. The dose can be increased to a maximum of 300 mg/day; however, doses >200 mg/day are associated with increased adverse effects and should be used cautiously. Amantadine is renally excreted, and the dose should be reduced in patients with renal impairment.[110] If the dyskinesias that L.M. is experiencing are tolerable but the duration of off-time is more problematic, then selection of another agent such as a COMT inhibitor or MAO-B inhibitor may be more appropriate than the initiation of amantadine at this time.

Side effects of amantadine mainly involve the gastrointestinal (eg, nausea, vomiting) and CNS (eg, dizziness, confusion, insomnia, nightmares, and hallucinations). Patients receiving concomitant anticholinergic therapy may experience more prominent CNS side effects.[111] Livedo reticularis, a rose-colored mottling of the skin

usually involving the lower extremities, can occur with amantadine as early as 2 weeks after initiating therapy. The consequences of livedo reticularis are entirely cosmetic, and discontinuation of therapy is unnecessary. Ankle edema may be seen in association with livedo reticularis. Elevation of the legs, diuretic therapy, and dosage reduction often alleviate the edema.

CATECHOL-O-METHYLTRANSFERASE INHIBITORS

COMT is an enzyme widely distributed throughout the body that is responsible for the biotransformation of many catechols and hydroxylated metabolites including levodopa. When carbidopa, an inhibitor of aromatic AAD, is coadministered with levodopa, the peripheral conversion of levodopa to dopamine via this pathway is inhibited. As a consequence, the conversion of levodopa to 3-*O*-methyldopa (3-OMD) by COMT is amplified and becomes the major metabolic pathway for levodopa degradation. The metabolite 3-OMD lacks antiparkinsonian activity and may compete with levodopa for transport into the circulation and brain. By preventing its peripheral degradation, the therapeutic effect of levodopa can be extended via inhibition of COMT.

Entacapone, tolcapone, and opicapone are selective, reversible, and potent COMT inhibitors that increase the amount of levodopa available for transport across the blood–brain barrier (**Fig. 59-3**) to prolong its therapeutic effect. Use of these agents is associated with increased on-time and a decrease in the daily levodopa dose.[111,112] The pharmacologic and pharmacokinetic effects of each COMT inhibitor are compared in **Table 59-5**.[111–117] Two uncontrolled trials and one controlled evaluation of patients with motor fluctuations newly placed on entacapone compared switching patients to tolcapone versus continuing the newly started entacapone. These trials alluded to the therapeutic benefits of tolcapone compared to entacapone; however, tolcapone is associated with cases of fatal, acute fulminant liver failure. This fatal as well as acute liver failure has led to stringent liver function monitoring requirements and limited clinical use. If initiated, liver function monitoring should be performed

at baseline and every 2 to 4 weeks for the first 6 months followed periodically thereafter as clinically necessary.[112] Because of the risks for hepatotoxicity associated with tolcapone, entacapone or opicapone are the preferred COMT inhibitors and either would be a good choice for L.M. if he desires an increase in his on-time.

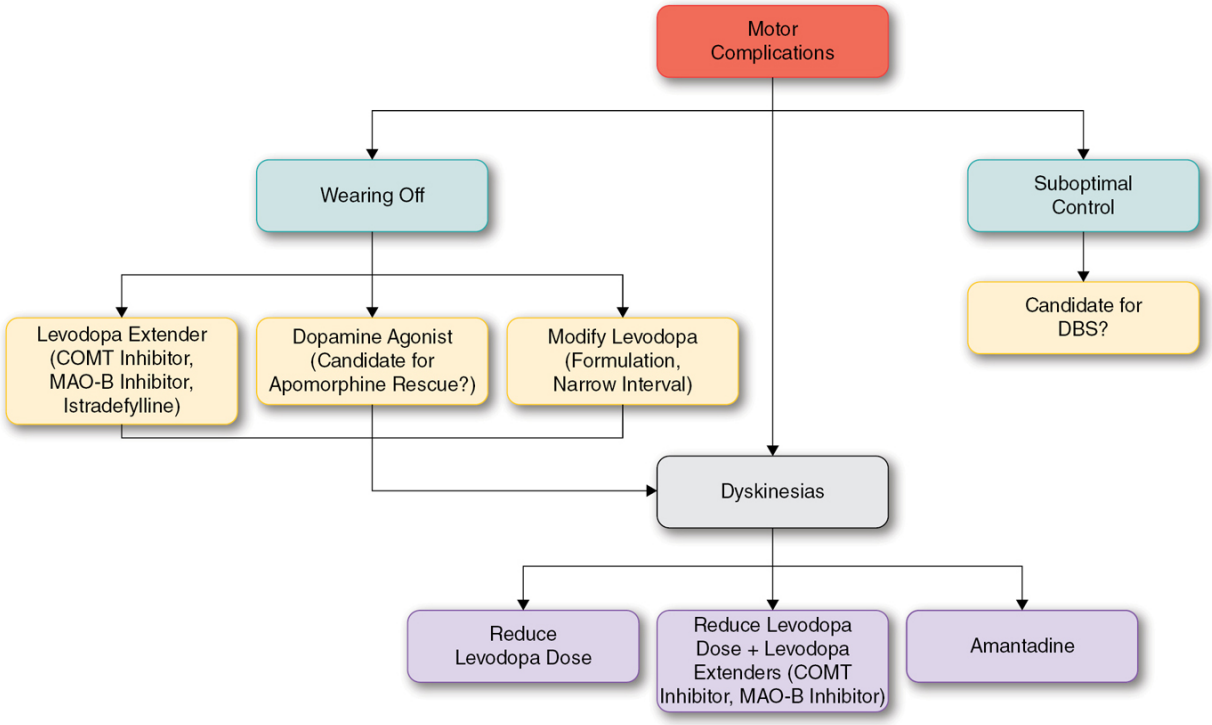

Figure 59-3 Suggested treatment algorithm for the management of motor complications in late Parkinson disease. *COMT, catechol-O-methyltransferase*; DBS, deep brain stimulation; MAO, monoamine oxidase.

Table 59-5
Pharmacologic and Pharmacokinetic Properties of Catechol-*O*-Methyltransferase Inhibitors

	Tolcapone	Entacapone	Opicapone
Bioavailability	65%	35%	Decreased by 62% following moderate fat/calorie meal
T_{max} (hours)	~2	1	2
Protein binding	>99.9%	98%	>99%
Metabolism	Glucuronidation; CYP3A4, CYP2A6; methylated by COMT	Isomerization, glucuronidation	Sulfation, glucuronidation, methylation (by COMT), reduction, and glutathione conjugation
Half-life (hours)	2–3	Biphasic; 0.4–0.7 (beta phase), 2.4 (gamma phase)	1–2
Excretion	Urine (60% metabolites, 0.5% unchanged); feces (40%)	Feces (90%); urine (10%)	Feces (22%), expired air (20%), urine (5% unchanged)
Time to reverse COMT inhibition (hours)	16–24	8	>5
Maximal COMT inhibition at 200-mg dose	>80%	65%	>84%
Increase in levodopa AUC	100%	35%	64%–94%
Increase in levodopa half-life	75%	85%	NA
Dosing method	tid, spaced 6 hours apart	With every administration of levodopa	Once daily

AUC, area under the curve; COMT, catechol-*O*-methyltransferase; CYP, cytochrome P-450; tid, three times daily.

Entacapone

Case 59-1, Question 15: Six months after adjusting the frequency of his carbidopa/levodopa dose and adding amantadine, L.M. reports that his dyskinesias are not too bothersome, but he is now having increased periods (lasting a few minutes) in which he cannot move. He is currently taking amantadine 100 mg twice daily, pramipexole 0.5 mg three times daily, and IR carbidopa/levodopa 25 mg/250 mg five times a day, but, "even on a good day," gains symptomatic relief for only about 2 to 3 hours after a dose. When should entacapone be initiated? How effective is entacapone for reducing the symptoms of PD?

Early initiation of a COMT inhibitor at the same time that levodopa is first introduced has been proposed as a way of reducing the development of levodopa-induced motor complications[115]; theoretically, this strategy should provide more stable plasma levels of levodopa and lessen pulsatile stimulation of striatal dopamine receptors normally observed with intermittent levodopa dosing. This strategy was tested in the Stalevo Reduction in Dyskinesia Evaluation in Parkinson's Disease (STRIDE-PD) study, a multicenter,

double-blind study that randomly assigned 747 patients to initiate either carbidopa/levodopa or carbidopa/levodopa/entacapone four times daily.[115] Surprisingly, patients randomly assigned to receive carbidopa/levodopa/entacapone actually had a shorter time to onset of dyskinesia (hazard ratio: 1.29; *P* = .04) and increased dyskinesia frequency at week 134 (42% vs 32%; *P* = .02). These findings may have been confounded by an increased use of dopaminergic therapy in the entacapone group. The findings of the STRIDE-PD study do not support the early administration of entacapone in combination with levodopa to reduce the occurrence of motor complications.

The efficacy and safety of entacapone as an adjunct to levodopa therapy in the presence of motor complications was established in two pivotal multicenter, randomized, double-blind, placebo-controlled trials.[116,117] Subjects for both studies had idiopathic PD with motor fluctuations, including wearing-off phenomena, despite maximal tolerated doses of levodopa. In both trials, patients were randomly assigned to receive either entacapone 200 mg or placebo (up to 10 doses/day) with each dose of carbidopa/levodopa.[116,117] In both trials, significant improvements in off-time (~1 hour), UPDRS scores (10% improvement), and levodopa doses (reductions of ~80–100 mg/day) were consistent.

Opicapone

Opicapone is the newest selective COMT inhibitor on the market approved by FDA in 2020 for adjunctive treatment in patients with PD experiencing “off” episodes. It boasts no major benefits over entacapone except for once-daily dosing making it more attractive and still seems to be safer than tolcapone. Two double-blind, randomized, parallel-group, placebo- and active-controlled and placebo-controlled trials were conducted over 14 to 15 weeks evaluating opicapone as adjunctive to levodopa therapy. The first study compared patients taking 50 mg (*N* = 115) versus placebo (*N* = 120) and showed mean decrease in absolute off-time of −1.95 hours (*P* = .002) as well as an increase in on-time without troublesome dyskinesia by 1.84 hours (*P* = .001).[118] The second study also

evaluated patients taking 50 mg of opicapone (*N* = 147) versus placebo (*N* = 135). Similar results were seen in mean decrease in absolute off-time of 1.98 hours (*P* = .008) and increased absolute on-time without troublesome dyskinesia of 1.43 hours (*P* = .065).[119] Opicapone may have some advantages over entacapone making it a more attractive first choice of COMT inhibitor. When compared to entacapone, opicapone provides a superior response as evidence by bioavailability of coadministered levodopa associated with more pronounced, long-lasting, and sustained COMT inhibition with only daily dosing.[120] One study evaluated the efficacy of switching from entacapone to opicapone 50 mg daily (*N* = 495) for a 1-year follow-up period. Switching from opicapone to entacapone, decreased the off-time further by 39.3 minutes over 1 year as well as those that did not switch maintained their efficacy.[121]

Dosing

CASE 59-1, QUESTION 16: The decision is made to gradually discontinue pramipexole as guided by symptoms or side effects. How should entacapone be dosed, and how does entacapone compare to opicapone?

Entacapone is approved for use as adjunctive therapy to levodopa for the treatment of PD in patients experiencing wearing-off or end-of-dose deterioration. It is given as one 200 mg tablet with each carbidopa/levodopa administration, up to eight tablets/day. It is available in a combination tablet with a 1:4 ratio of IR carbidopa/levodopa that patients can be switched to once they are stabilized on individual formulations of carbidopa/levodopa and entacapone. As for opicapone, it is dosed 50 mg tablet daily at bedtime without food 1 hour before and at least 1 after administration for adjunctive therapy to levodopa for PD in patients experiencing wearing-off. For patients with moderate liver dysfunction, the dose can be reduced to 25 mg daily and avoided in severe liver impairment. Opicapone has decreased C_{max} up to 62% when administered with food and should be administered 1 hour before or

after food. If dyskinesias occur, it may be necessary to lower the levodopa dose by ~10% to 25% particularly if the patient is receiving >800 mg/day of levodopa. Although pramipexole is being discontinued in L.M., he should still be monitored for dyskinesias, especially during the first few weeks of therapy, as it may also be necessary to lower his carbidopa/levodopa dose.

Adverse Effects

CASE 59-1, QUESTION 17: What are the adverse effects of entacapone, and how should they be managed?

Most COMT inhibitor adverse effects are associated with increased levodopa exposure. For example, entacapone-induced adverse effects include dyskinesias (50%–60%), dizziness (10%–25%), nausea (15%–20%), and hallucinations (1%–14%).[116,117] To circumvent these effects, reducing the levodopa dosage by 10% to 15% is a successful strategy in about one-third of patients experiencing dyskinesias. Other adverse effects include urine discoloration (11%–40%), diarrhea (10%), and abdominal pain (6%).[116,117] Urine discoloration (brownish orange) is attributed to entacapone and its metabolites and is considered benign, but patients should be counseled regarding this effect. The most common reason for the withdrawal of entacapone from clinical studies and discontinuation of therapy was severe diarrhea (2.5%).[122] Although the results of the STRIDE-PD study indicated that patients taking the combination of carbidopa/levodopa/entacapone may be at an increased risk for cardiovascular events (eg, heart attack, stroke, and cardiovascular death) compared with those taking carbidopa/levodopa, subsequent FDA analysis has found no increased risk.[123]

MONOAMINE OXIDASE-B INHIBITORS

Selegiline

Selegiline may have a role as a symptomatic adjunct to levodopa in more advanced disease. Studies have found improvement in the wearing-off effect in 50% to 70% of patients and a reduction in as much as 30% in the total daily dose of levodopa without improvements in on-time.[124,125] This improvement has also been shown to arrive with an initial worsening of dyskinesis in 60% of treated patients, which may be counteracted with levodopa dose reductions. Selegiline has been shown to reduce off-time by 32% (2.2 hours) compared with 9% (0.6 hours; $P < .001$) for placebo in a 12-week, randomized, multicenter, parallel-group, double-blind study but was not reproducible in an identical trial.[126,127] Authors hypothesize that this conflict may be due in part to large and potentially variable placebo effects seen in PD trials. The on–off effect is less responsive to the addition of selegiline.

Rasagiline

Rasagiline has also been studied as an adjunct to levodopa in advanced disease. When added to levodopa therapy, rasagiline can improve motor fluctuations, reducing off-time by 1.4 hours and 1.8 hours (for the 0.5- and 1-mg/day groups, respectively) compared with 0.9 hours for placebo.[128] Patients treated with 0.5 mg/day and 1 mg/day of rasagiline had 0.49 hour (0.08–0.91; $P = .02$) and 0.94 hour (1.36–0.51; $P < .001$) less off-time compared with placebo. Significant improvements were reported in the UPDRS subscores for ADLs in the off-state and motor performance in the on-state as well as clinician global assessments. Dyskinesias were slightly worsened in the 1-mg/day group. As adjunctive therapy to levodopa, rasagiline appears to provide similar benefit to entacapone.[128] In the lasting effect in adjunct therapy with rasagiline given once daily (LARGO) study when compared with entacapone 200 mg administered with each levodopa dose, rasagiline 1 mg/day reduced total daily off-time in a similar manner (decrease of 21% or 1.18 hours for rasagiline and 21% or 1.2 hours for entacapone).[129] Reduction of levodopa dose may be necessary if dyskinesias occur when rasagiline is added in combination with levodopa.

Safinamide

Safinamide (Xadago™) was approved by the FDA in May 2017 as an adjunct to carbidopa/levodopa for patients experiencing "off" episodes. It is not approved as monotherapy but found to be effective in randomized controlled trials for motor complications in PD when used as adjunctive treatment with levodopa. Compared with placebo, safinamide increased mean daily "on" time without troublesome dyskinesia and improved motor function. A 24-week trial of 549 patients with PD taking oral levodopa who had "off" time ≥1.5 hours per day found that treatment with safinamide increased the mean on-time without troublesome dyskinesia by ~1.4 hours compared with 0.6 hours for placebo.[130,131] The side effect profile is similar to rasagiline (see Table 59-2). Patients should additionally be monitored for visual changes as retinal detachment and loss of photoreceptor cells were noted in animal studies. The list of contraindicated medications is extensive and should be reviewed prior to starting therapy. Safinamide has a half-life of 20 to 26 hours, reaches a steady state in 5 to 6 days, and can be taken without regard to meals. It requires hepatic dose adjustment but no renal dose adjustments. The extent of use in clinical practice and eventual place in therapy are unknown at this time.

Istradefylline

Istradefylline (Nourianz™) is a mechanistically novel agent used as an adjunct treatment to carbidopa/levodopa for patients that develop "off" episodes. It was FDA-approved in April 2019. Istradefylline is a selective adenosine receptor agonist that exerts its action via adenosine A_{2A}. Originally denied by FDA in 2008 because of lack of follow-up data, istradefylline was later approved in Japan in 2013. Thereafter, four clinical studies lasting >12 weeks and included >1100 participants evaluated istradefylline versus placebo for adjunctive therapy to carbidopa/levodopa. In a 2008 study including 196 patients, a decrease of daily awake off-time for istradefylline had a mean of −10.8 ±16.6% (95% CI: −13.46 to −7.52) from baseline compared with −4.0 ±15.7% (95% CI: −7.73 to 0.31; *P* = .007) for

placebo.[13] One study published in 2016 showed a trend toward a greater decrease in daily off-time versus placebo for both the 20 mg and 40 mg doses, but statistical significance was not reached.[132] In 2018, an analysis of a postmarketing surveillance data was conducted in Japan, in 476 patients. This study showed the drug was effective in 61.3% of patients treated with istradefylline, based on the physician's global assessment, as well as UPDRS III scores were reduced by 33.7 to 30.3 from baseline. This analysis also showed that off-time was reduced in 38.2% of patients, and off-time symptoms improved in 44.7% of patients while motor dysfunction was improved in 48.5% of patients.[133] Lastly, a meta-analysis reviewed six randomized studies and concluded that istradefylline at 20 mg/day improved UPDRS III as well as at 40 mg/day improved both off-time and UPDRS III.[134] All trials revealed that this medication is well tolerated with dyskinesia and hallucinations being the most reported adverse events.[133]

Surgical Therapies for Parkinson Disease

Case 59-1, Question 18: L.M. is now classified as Hoehn and Yahr[2] late stage 3. He is now on amantadine 100 mg twice daily, IR carbidopa/levodopa 25 mg/250 mg five times daily, and entacapone 200 mg five times daily with carbidopa/levodopa administrations. His overall control of his PD has diminished greatly in the last couple of months. His on-time averages around 6 hours/day with the majority of it accompanied by troublesome dyskinesias. Most days he needs some assistance with ADLs. His cognitive function remains well preserved, and he is not depressed. He has heard about surgical procedures that might benefit patients with PD. Is surgical therapy superior to medical therapy in patients with advanced PD?

Two types of surgical therapies have been used in patients with advanced PD who cannot be adequately controlled with medications. The first involves making an irreversible surgical lesion in a specific location in the brain (eg, posteroventral pallidotomy or stereotactic thalamotomy). The second involves surgical implantation of a device that sends electrical impulses to specific parts of the brain (eg, deep

brain stimulation [DBS]). Posteroventral pallidotomy has been shown to reduce dyskinesias on the contralateral side and may permit the use of higher dosages of levodopa for managing rigidity and bradykinesia.[135] A significant disadvantage, however, is the need to make a lesion near the optic tract, which may risk visual loss. Other possible risks of pallidotomy include weakness, paralysis, and hemorrhage that can cause stroke as well as speech difficulty. Stereotactic thalamotomy has been shown to reduce symptoms of debilitating tremor and improve rigidity in patients with PD.[136] This intervention has eliminated contralateral tremor in 80% of patients, and improvement has been sustained for up to 10 years. As with pallidotomy, a disadvantage of thalamotomy, however, is the need to make an irreversible lesion in the basal ganglia that may limit the effectiveness of newer procedures because they become available. Thus, DBS is now the preferred surgical method for treating advanced PD that cannot be adequately controlled with medications. DBS uses an implanted electrode in the brain, in either the subthalamic nucleus (STN) or the globus pallidus interna (GPi), which is connected to a subcutaneously implanted pacemaker. This implanted electrode permits the delivery of high-frequency stimulation to the desired target. Advantages of DBS include no need for an irreversible brain lesion, and it provides flexibility for altering the target site and program stimulation parameters.

The efficacy of DBS in advanced PD was shown in a two-part study of 255 patients with idiopathic PD responsive to levodopa but with persistent and disabling motor symptoms.[137] Patients were randomly assigned to DBS or best medical therapy and followed for 6 months. Patients receiving DBS gained a mean of 4.6 hours/day of on-time without troubling dyskinesias compared with 0 hours/day for best medical therapy ($P < .001$). Additionally, 71% of patients receiving DBS experienced clinically meaningful motor function improvements (≥5-point change in UPDRS motor score) compared with only 32% of patients receiving best medical therapy ($P < .001$).[137] Patients whose goal is to reduce the amount of dopaminergic agents needed for symptoms control STN is the preferred intervention. On the other hand, if there are additional

concerns for depression, cognitive decline, and/or reduced medication dyskinesias, use of GPi is then the preferred DBS intervention.[138–142]

Case 59-1, Question 19: What surgical therapy would be most appropriate for L.M.?

L.M. appears to be an ideal candidate for DBS. Candidates for DBS should have idiopathic PD and be levodopa-responsive but continue to experience motor complications or tremor despite optimal pharmacotherapeutic regimens. Ideally, DBS should be avoided in patients with preexisting cognitive or psychiatric problems owing to a slight risk of decline in cognition. No strict age limitation for DBS exists, but patients younger than age 70 years, such as L.M., appeared to recover from surgery more quickly and showed greater motor improvements. DBS of the STN consistently demonstrates a marked reduction in the need for escalating levodopa dosages compared with GPi DBS,[138–143] but data suggest other nonmotor symptoms such as visual processing speed and depression may be affected more favorably when targeting the GPi.[139]

Investigational Pharmacotherapy

CASE 59-2

Question 1: K.B. is a 61-year-old female who presents to the movement disorders clinic after referral from her family doctor for a presumptive diagnosis of PD. She is Hoehn and Yahr[2] stage 1 with slightly decreased arm swing on the left side and unilateral resting hand tremor. Her past medical history is significant for hypertension and mild renal insufficiency (serum creatinine of 1.4 mg/dL). Since her initial visit with her family physician, she has been researching information about alternative PD treatments from several PD-related websites.

Are there any dietary supplements or other investigational therapies that may benefit K.B.?

DIETARY SUPPLEMENTS

Multiple mechanisms have been implicated in the development of PD and, thus, have produced a variety of dietary supplements studied as possible alternatives or neuroprotective agents. These supplements have been hypothesized to benefit patients with PD as antioxidants by scavenging free radicals, prevention of mitochondrial dysfunction, reduction of neuronal inflammation, and modulation of neurons to slow down apoptosis as well as cell degeneration. Despite numerous studies, many supplements fall short of being viable options as effective alternative treatments. For this reason, many supplements may not provide the expected benefit, but they can be utilized in patients seeking alternative options in the context of medication intolerance.

Coenzyme Q10

A study in untreated patients with PD provided coenzyme Q_{10} (CoQ_{10}) failed to show statistical significance but met the threshold for futility. Two subsequent phase III trials of patients with early PD failed to show symptomatic or neuroprotective benefits.[143–145] In an evaluation of 600 patients with early PD, subjects were randomized to receive either 1200- or 2400-mg of CoQ_{10} daily in addition to 1200 IU of α-tocopherol. The study was terminated prematurely because of failure to meet prespecified futility endpoints and trend in adverse outcomes compared to placebo.[145]

Creatine and minocycline

Minocycline (anti-inflammatory and antiapoptotic properties) and creatine (an antioxidant and enhances mitochondrial energy production) were evaluated to determine both safety and if either slowed the progressive decline in function associated with PD. The use of both creatine and minocycline in PD was examined in a futility-design study, which patients with early PD not requiring therapy were randomly assigned to receive creatine 10 g/day, minocycline 200 mg/day, or placebo.[146] After 12 months, the mean

change in the total UPDRS could not be rejected as futile and met the criteria for further clinical testing. A long-term follow-up to this trial found that by 18 months, patients requiring symptomatic treatment did not differ, but significantly more patients on minocycline discontinued therapy prematurely (23% vs 9% of creatine and 6% of placebo patients) because of gastrointestinal discomfort within 30 to 60 days postinitiation. Given the unresolved issues surrounding the induction of antibiotic resistance with long-term use of an agent such as minocycline and concerns for tolerability, it is generally not recommended. A long-term, randomized, double-blind, placebo-controlled trial of creatine 10 g/day versus placebo in early treated PD was terminated early for futility based on an interim analysis. The trial concluded that treatment with creatine for at least 5 years does not support its use in PD.[147]

Vitamins

Multiple studies have found a relationship between vitamins and PD. Vitamins may play a role as antioxidants and affect biologic functions by regulating gene expression, which may be beneficial for the treatment of PD. The B vitamins and vitamin C have evaluated their neuroprotective benefits for PD with little evidence to support these claims.

The most comprehensive evaluation of antioxidant therapy for PD comes from the DATATOP study.[67,124,148] In this study, patients with early PD were assigned to one of four treatment regimens: α-tocopherol (vitamin E 2000 international units [IU]/day) and selegiline placebo; selegiline 10 mg/day and α-tocopherol placebo; selegiline and α-tocopherol active treatments; or dual placebos. After ~14 months of follow-up, no difference was seen between the α-tocopherol group and placebo group in time to require levodopa.[67] Thus, despite the theoretic benefit, clinical data are lacking to support the routine use of α-tocopherol, and it would not be recommended in K.B.[7]

In contrast, vitamins D and B_{12} may hold some promise in PD. A recent 2020 cohort study has shown that higher levels of B_{12} were observed in patients with PD who did not develop dementia.[149] Vitamin B_{12} cutoff of <587 ng/L was 87% sensitive and 70% specific (95% CI: 0.60–0.98) in determining patients with dementia. Patients with PD and vitamin B_{12} levels <587 ng/L were 5.4 times more likely to develop dementia with half having dementia within 5 years of PD diagnosis versus 11% in those with a vitamin B_{12} level of ≥587 ng/L ($P < .05$).[150] A study using a drug reimbursement database conducted over 29 years in 3173 individuals found 50 cases of PD. Vitamin D_3 levels were evaluated based on frozen samples collected at baseline and showed that higher levels of vitamin D_3 are related to a lower risk of developing PD, which has a potential to be neuroprotective effect in PD.[151] Additionally, a randomized, double-blind, placebo-controlled trial reviewing vitamin D_3 supplementation (1200 IU/day for 12 months) in patients with PD significantly prevented the deterioration of PD.[152]

Omega-3 fatty acids

Omega-3 fatty acids have a long history of research in neuronal health, including neuroprotective properties, anti-inflammatory activity, antiapoptotic activity, and enhanced synthesis of brain-derived neurotrophic factor (BDNF). A pilot study of 31 individuals studied the effects of omega-3 fatty acids in patients with PD and with depression leading to improvements in the Montgomery–Asberg Rating Scale for depression and Clinical Global Impression-Depression Score.[153] These same improvements were unfortunately not seen on the Beck Depression Inventory score. In patients who may already be inclined to take omega-3 fatty acid supplements, there may be some additional benefits in improving mood and depressive symptoms.

EMERGING THERAPIES

With developments in PD research and biopharmaceutical technology, new treatment targets and modalities are constantly being investigated, including new disease-modifying targets, tetrahydrocannabinol (THC), nabilone (synthetic cannabinoid), cannabidiol (CBD) treatments, and stem cell transplant.

Disease-modifying targets include transcription factors, proteins, and their mutations. Novel pharmaceutical and biologic technologies under development include small-molecule drug delivery such as with glial cell–derived neurotrophic factor, stem cell therapies, and nerve cell grafts. Phase 2 and 3 clinical trials are currently underway exploring molecular targets such as GLP-1, LRRK2, α-synuclein, and GBA, which may provide a breakthrough in the development of disease-modifying therapies in PD.[154,155]

Growing research related to the benefits of CBD in PD is emerging. Cannabidiol (Epidiolex®) was evaluated in an open-labeled, dose escalation study in 13 patients with PD to establish its safety and tolerability along with its impact on common PD symptoms. Doses were titrated from 5 mg/kg/day up to 25 mg/kg/day but subsequently reduced to a maximum dose of 20 mg/kg/day as a result of adverse events in about a third of patients.[155] The most common adverse effects reported were diarrhea (85%), somnolence (69%), fatigue (62%), transaminitis (38.5%), and weight gain (31%) as well as 23% of patients discontinuing therapy because of intolerability. Although not a primary outcome, improvements in UPDRS scores were seen in the 10 patients that completed the study along with nighttime sleep and emotional/behavioral dyscontrol scores. One meta-analysis included three studies that evaluated nabilone, CBD, and THC in patients with PD. Nabilone was noted to improve Parkinson dyskinesia, whereas CBD and THC products did not show improvement in dyskinesias, but CBD did show an improvement in daily living activities.[156]

Lastly, stem cell transplantation to replace destroyed dopaminergic neurons to treat PD is being evaluated. It has been identified that abnormalities of protein misfolding in stem cell–derived neurons from patients with PD may be reversed by manipulating genes or exposing the cells to drug-like molecules. In vivo transplantation of

the neurons from a mini-substantia niagra–like structure have resulted in early and progressive amelioration of PD in rats.[157]

Nonmotor Symptoms of Parkinson Disease

Although PD is mostly recognized for its cardinal features of motor dysfunction, nonmotor symptoms are an important part of the disease throughout all stages and are a key determinant of quality of life (**Table 59-6**).[158] More than 98% of patients with PD have at least one nonmotor symptom. The average per patient is nearly eight with the number and impact increasing with disease duration and severity.[159] Common nonmotor symptoms include autonomic dysfunction (eg, gastrointestinal disorders, orthostatic hypotension, sexual dysfunction, urinary incontinence, sialorrhea, seborrhea, and constipation), sleep disorders (eg, RLS, periodic limb movements of sleep [PLMS], excessive daytime somnolence, insomnia, REM sleep behavior disorder), fatigue, and psychiatric disorders (eg, dementia, depression, and anxiety).[159] In one longitudinal study of patients with PD, the most common nonmotor symptoms were psychiatric symptoms (68%, most commonly anxiety), fatigue (58%), leg pain (38%), insomnia (37%), urinary symptoms (35%), drooling (31%), and difficulty concentrating (31%).[159] Regular screening for these nonmotor symptoms should occur. L.M. has a history of depression treated with citalopram that could be attributable to PD, and his therapy should be periodically evaluated. The forgetfulness and decreased memory described by L.M. could be early signs of cognitive decline and warrant close observation.

Table 59-6
Nonmotor Symptom Management

Nonmotor Symptoms	Potential Interventions
Central nervous system	
Cognitive impairment/dementia	Reduce anticholinergic agents, cholinesterase inhibitor.
Fatigue	Caffeine, CNS stimulant, amantadine, encourage sleep

	hygiene or refer to specialist.
Daytime sleepiness	Encourage sleep hygiene, reduce dose of dopamine agonist, bright light therapy, exercise, refer to specialist.
Behavioral	
Psychosis	Reduce or discontinue anticholinergic agent and/or dopamine agonist. Antipsychotics (eg, quetiapine, clozapine, pimavanserin).
Impulse control disorder	Reduce or discontinue dopamine agonist. Add clozapine, quetiapine, or naltrexone.
Anxiety	Reduce dose or discontinue contributing agents, cognitive behavioral therapy, selective serotonin-reuptake inhibitors, minimize off-times.
Depression	Selective serotonin-reuptake inhibitor, newer-generation serotonin norepinephrine-reuptake inhibitor, cognitive behavioral therapy
Sleep related	
Insomnia	Reduce or discontinue activating agents. Add trazodone, melatonin, nonbenzodiazepine hypnotic. Encourage sleep hygiene, refer to specialist. Note: Avoid agents on Beer list in patients >65.
REM sleep behavior disorder	Clonazepam, melatonin
Musculoskeletal	
Falls	Referral to physical therapy and/or occupational therapy, aid with ambulation, minimize risk for bone fractures, treat osteoporosis, reduce or remove sedating agents.
Dysphagia	Referral to speech therapist, dysphagia diet, avoid anticholinergic medications, manage dry mouth.
Pain	Appropriate treatment for type of pain, minimize off-times, physical therapy, referral to pain specialist
Autonomic dysfunction	
Orthostatic hypotension	Reduce dose of α-blockers, dopamine agonist, diuretics, vasodilators, psychotropics. Encourage sodium and fluid intake, fludrocortisone, midodrine, droxidopa, pyridostigmine.
Constipation	Fiber (supplement or dietary), probiotics, hydration,

	exercise, laxatives, enema, stool softeners, new drug therapies (Amitiza®, Linzess®, Trulance®)
Overactive bladder	Behavioral therapies (eg, bladder training, fluid management, pelvic floor muscle exercises), antimuscarinic agents, mirabegron, intradetrusor injections of botulinum toxin
Sialorrhea	Local injection of botulinum toxin, atropine sublingual drop, glycopyrrolate, ipratropium sublingual spray
Rhinorrhea	Avoid food triggers, ipratropium nasal spray, anticholinergic agent.
Seborrhea	Avoid alcohol-containing skin products and hard soaps, encourage consistent skin care, refer to dermatologist.
Sexual side effects	Sildenafil, tadalafil, vardenafil

DEMENTIA

CASE 59-3

Question 1: J.D. is a 74-year-old male with advanced PD, Hoehn and Yahr[2] stage 4. During the last year, his family has noticed that he is increasingly forgetful and anxious. Twice recently, he left home alone for brief periods and called 911 because he thought someone was trying to break into the house. He also calls his daughter two or three times each day, often repeating the same questions and forgetting that he called her earlier. His wife is his primary caregiver, and he is nearly entirely reliant on her for help in performing ADLs. He scored 20 (below normal) on his most recent Mini-Mental Status Examination, and his family reports that he is no longer interested in social activities or hobbies. Neuropsychiatric testing is performed and demonstrates a significant depressive component to his dementia. Subsequent recommendations from the neuropsychiatrist are that he receives 24-hour supervision, along with participation in structured leisure activities including adult day care for several hours/week to help relieve his wife's caregiver burden.

What is the best treatment for progressive cognitive decline that J.D. is experiencing?

Approximately 48% to 80% of patients may develop dementia during their disease course at a rate of about six times greater than healthy individuals.[20,160] One longitudinal study of 136 incident cases

of PD followed for 20 years found that nearly 100% eventually exhibited dementia.[161] The prevalence of cognitive decline and dementia among patients with PD ranges from 10% to 30% and may be associated with a more rapid progression of disease-related disability.[7] Successful management of cognitive impairment in patients with PD first requires that all potentially reversible causes and underlying contributing factors be addressed. These include treating infections, dehydration, and metabolic abnormalities as well as eliminating unnecessary medications (particularly anticholinergics, sedatives, and anxiolytics) that can exacerbate dementia or delirium.

Experience with cholinesterase inhibitors for treating cognitive impairment in PD indicates marginal improvements with their use.[162–164] Two randomized, controlled trials evaluated donepezil have failed to show consistent benefit, whereas galantamine has only been evaluated in a single open-label trial.[165,166] Rivastigmine was found to provide clinically meaningful (moderate or marked improvement on the Alzheimer's Disease Cooperative Study–Clinician's Global Impression of Change) benefit to significantly more patients than placebo in a large, randomized, placebo-controlled trial and has demonstrated sustained cognitive benefit for up to 48 weeks.[164,167,168] As a result, rivastigmine was FDA-approved for the management of mild-to-moderate dementia in PD and is, therefore, the drug of choice. Compared with placebo, the cholinesterase inhibitors often result in statistically significant changes on cognitive scales. Their impact on function and disposition, however, is unclear.

A cholinesterase inhibitor such as rivastigmine may be considered for patients such as J.D., although he must be monitored closely for signs of deterioration of motor function such as worsening of tremor.[165] Cholinesterase inhibitors are associated with other adverse events that may be overlooked and attributed to the PD itself, including sialorrhea, excessive lacrimation, incontinence, nausea, vomiting, and orthostasis. Perhaps more important than any medication therapy, adequate social support for J.D. should be ensured. Because he becomes further dependent on family members for assistance with ADLs, the increased needs of the

caregiver(s) should also be considered. In the case of J.D., attending adult day care several times weekly, if available, would provide a structured, supervised environment for interaction with others as well as providing a rest period for his caregiver. Dementia is a leading cause of nursing home placement for patients with PD.[165]

Although not a cholinesterase inhibitor, memantine is commonly used for the treatment of moderate-to-severe dementia. In a 24-week randomized, placebo-controlled trial, patients with dementia with Lewy body (DLB) had improvement in global clinical improvement; on the other hand, there was no significant difference from placebo in those with PD dementia (PDD).[169] A later meta-analyses revealed patients with PDD may see benefits in attention, processing speed, and executive functions with memantine use. In clinical trials, memantine has been shown to be well tolerated in patients with DLB and PDD.[170] Unfortunately, hallucinations and worsened neuropsychiatric symptoms have occasionally been reported, which has led to be cautious in this patient population.

DEPRESSION/ANXIETY

Case 59-3, Question 2: How should anxiety and depression be treated in J.D.?

Depression is often poorly recognized and inadequately treated in patients with PD.[166] This fact is likely because of the overlapping symptoms of depression and PD, which confound the identification of depression. Withdrawal, lack of motivation, flattened affect, decreased physical activity, and bradyphrenia are examples of overlapping features.[166]

Treatment of depression in patients with PD should first focus on providing adequate symptomatic treatment to restore mobility and independence as depression can be attributed to lengthy off-periods. Antiparkinsonian drugs, such as pramipexole, can be associated with mood-enhancing effects independent of their ability to reduce the time in the off-state.[166] Case reports and small trials have shown

that depression in patients with PD can be successfully treated with antidepressant drugs, including tricyclic agents (eg, amitriptyline, desipramine, nortriptyline), bupropion, and selective serotonin-reuptake inhibitors (SSRIs) (eg, citalopram and paroxetine).[166] Given the overall poor quality of clinical trials, it is difficult to know whether these desirable outcomes reflect a class effect or are unique to each individual agent. Some antidepressants may worsen symptoms in patients with PD. For example, fluoxetine can be activating and worsen agitation; nevertheless, SSRIs have been shown to worsen PD tremor in ~5% of patients.[171] With tricyclic antidepressants (TCAs), care must be taken to observe for anticholinergic side effects that may worsen PD symptoms such as impaired cognition, delayed gastric emptying (which may reduce levodopa effectiveness by increasing levodopa degradation in the gut), urinary problems, orthostatic hypotension, and increased risk of falls. Additionally, consideration should be taken for the risk of drug–drug interactions and serotonin syndrome associated with the combination of SSRIs or TCAs with concomitant MAO-B inhibitors. Electroconvulsive therapy may also be considered in refractory cases but may adversely affect cognition.

Based on his symptoms, it is reasonable to start J.D. on an antidepressant. Clinical experience suggests selecting initially an SSRI, which balances efficacy and safety. For other patients with depression, the drug of choice should be individualized based on other pragmatic factors such as cost, potential for adverse effects, and personal or family response to prior agents. Regardless of which agent or class of antidepressant selected, therapy should be started at the lowest dose and gradually titrated to effect. He should be monitored closely for side effects particularly anticholinergic symptoms from TCAs and for any adverse effects related to mobility. He should be observed carefully for changes in parkinsonian symptoms, including the development of extrapyramidal symptoms as well as any signs of psychomotor agitation. Short-term use of benzodiazepines, such as lorazepam or alprazolam, may be provided to relieve anxiety symptoms but used cautiously for a limited time because of adverse effects related to cognition and risk

of falling as well as addiction potential.[172] Generally, anxiety symptoms should improve with treatment of the underlying depression.

PSYCHOSIS

In PD, the incidence of psychotic symptoms increases with age, cognitive impairment, and disease duration.[173] Other risk factors include higher age at PD onset, high doses of dopaminergic drugs, and REM sleep behavior disorder.[174] Symptoms are often more pronounced at night (the “sundowning” effect), and hallucinations are typically visual. As with the management of cognitive impairment, it is important to eliminate or minimize any potential causative factors or polypharmacy, particularly anticholinergic medications that could be contributing to the hallucinations or delirium. In some patients, reducing the dose of levodopa improves mental function and also provides satisfactory control of motor features. If it is not possible to achieve a balance between preserving motor control and decreasing neuropsychiatric symptoms through reduction in levodopa dosage, antipsychotics may be considered.

Older antipsychotic medications, such as haloperidol, perphenazine, and chlorpromazine, block striatal dopamine D_2 receptors as well as may exacerbate parkinsonian symptoms and are not recommended. Newer atypical antipsychotics are more selective for limbic and cortical D_3, D_4, and D_5 receptors. They have minimal activity at D_2 receptors and may control symptoms without worsening parkinsonism. Of these agents, clozapine has the best evidence of efficacy in patients with PD without adversely affecting motor function and should be preferentially considered.[161] However, its use is complicated by the need for frequent monitoring of white blood cell counts because of the risk of agranulocytosis. Other newer agents, particularly quetiapine controls psychosis without worsening parkinsonism.[20,165] Both risperidone and olanzapine worsen parkinsonism and are inferior to clozapine in patients with PD.[165,175] Aripiprazole has been associated with worsening motor function in patients with PD, whereas experience with ziprasidone has yielded

mixed results.[176] A newer atypical antipsychotic, pimavanserin, was FDA-approved based on results from one randomized, placebo-controlled trial. It acts through serotonin receptors and avoids interactions with dopamine receptors responsible for the worsening of PD symptoms as seen with other antipsychotics. It is not without its own risks, including cardiovascular and paradoxical worsening of psychosis.[177]

AUTONOMIC DYSFUNCTION

Patients with PD frequently experience dysautonomia, including orthostasis, erectile dysfunction, constipation, nocturia, sensory disturbances, dysphagia, drooling, seborrhea, and thermoregulatory imbalances. Management of these symptoms is generally supportive, and appropriate medical interventions similar to those used in other geriatric patients can be used to treat these symptoms whenever encountered. In some cases, fludrocortisone or midodrine can be considered if orthostatic hypotension is severe, although these drugs have not been well studied in patients with PD specifically.[158] Other possibly effective treatments for symptoms of autonomic dysfunction include sildenafil for erectile dysfunction and polyethylene glycol for constipation.[159]

FALLS

Patients with PD and their caregivers should be counseled on the prevention of falls because they can result in serious morbidity and mortality. Generally, falls result from one of several factors, including postural instability, freezing and festination, levodopa-induced dyskinesia, symptomatic orthostatic hypotension, coexisting neurologic or other medical disorders, and environmental factors. Prevention remains the best strategy and includes environmental precautions such as proper lighting, use of handrails, removing tripping hazards, and incorporating physical and occupational therapy. Reversible causes of postural or gait instability should be addressed whenever suspected. Patients with PD are advised to

take a vitamin D supplement to reduce their risk of fracture with future falls.[20]

SLEEP DISORDERS

Sleep disorders may occur at any time during the disease course and may even precede motor symptom development.[20] Excessive daytime drowsiness is a common sleep disorder in PD, which may be treated with modafinil.[158] Other sleep disorders such as insomnia, sleep fragmentation owing to PD symptoms, RLS, and REM sleep disorder (characterized by vivid dreams that are often acted out especially if frightening) are common and a source of decreased quality of life. When sleep dysfunction can be directly attributed to PD symptoms such as akinesia, tremor, dyskinesia, or nightmares, dosage adjustment of dopaminergic medications is indicated. Proper sleep hygiene should be encouraged. Insomnia symptoms unrelated to PD symptoms are treated similar to patients without PD and can be managed supportively.

RESTLESS LEGS SYNDROME AND PERIODIC LIMB MOVEMENTS OF SLEEP

Clinical Presentation

CASE 59-4

QUESTION 1: J.J., a 47-year-old female, presents to her family physician reporting daytime fatigue and difficulty sleeping at night because of "jumpy legs." She reports being able to sleep only 4 to 5 hours/night because of leg restlessness and feels unrefreshed after sleep. On further questioning, she describes the sensation in her legs as being like "bugs crawling under the skin." The sensation is not painful. She explains that the symptoms worsen in the evening and at night and are partially relieved with walking. She recalls that her mother had similar symptoms. Her spouse notes that she often "kicks" him in her sleep. Review of her medical history shows an otherwise healthy postmenopausal female.

What signs and symptoms are suggestive of RLS in J.J.? What laboratory tests or diagnostic procedures should be performed in J.J. to evaluate her condition?

RLS, also known as Willis–Ekbom disease, is a disabling sensorimotor disorder with an estimated prevalence of ~3.9% to 14.3% of the adult population and generally increases by age.[178] Although most patients with mild symptoms will not require treatment, RLS can be associated with adverse health outcomes, including sleep-onset insomnia, missed or late work, anxiety, depression, marital discord, and even suicide in severe cases.

Four essential criteria have been established by the International Restless Legs Syndrome Study Group to diagnose RLS (**Table 59-7**).[179] The pathognomonic trait of RLS is an almost irresistible urge to move the legs (akathisia), often associated with uncomfortable paresthesias or dysesthesias felt deep inside the limbs. Patients describe the sensation as "creepy-crawly, tingling, pulling, or painful" deep inside the limbs or "like soda water in the veins."[180] The symptoms may occur unilaterally or bilaterally, affecting the ankle, knee, or entire lower limb. With progressive disease, symptoms can begin earlier in the day, and progressive involvement of the arms or trunk may occur. Temporary or partial relief of symptoms can be achieved with movement. If patients attempt to ignore the urge to move the legs, akathisia will progressively intensify until either they move their legs or the legs jerk involuntarily.[180] Insomnia, especially having difficulty initiating sleep, is the most common reason for a patient with RLS to seek medical attention. Symptoms usually manifest in a circadian pattern with onset or worsening during nighttime hours (usually between 6 PM and 4 AM, with peak symptoms between midnight and 4 AM). The circadian pattern persists even in patients with inverted sleep–wake cycles. As a result of their symptoms, patients with RLS become "nightwalkers," spending significant time walking, stretching, or bending the legs in an effort to relieve symptoms.

Table 59-7

Clinical Features of Restless Legs Syndrome

Essential Criteria
Urge to move legs, associated with paresthesias or dysesthesias
Relief of symptoms with movement
Onset or exacerbation of symptoms at rest
Onset or worsening of symptoms during nighttime
Supportive Clinical Features
Accompanying sleep disturbance (sleep-onset insomnia)
Periodic leg movements
Positive response to dopaminergic therapy
Positive family history of RLS
Otherwise normal physical examination

RLS, restless legs syndrome.

The symptoms described by J.J. are an example of a classic presentation of RLS. The prevalence of RLS increases with age and is twice as more common in females than males.[181] She describes “creepy-crawly” sensations that are relieved partially with walking, a core feature of RLS. Her symptoms are worse during the evening hours. J.J. reports that her mother suffered from similar symptoms. The observation of a familial tendency suggests a genetic component, and several chromosomal loci have been linked to the disease.[182] A strong family history of RLS appears to correlate with an early age of onset (<45 years), whereas presentation at a later age is associated with more neuropathy and accelerated disease progression.[180]

Most cases of RLS are considered primary or idiopathic; therefore, the diagnosis does not require elaborate laboratory tests or diagnostic procedures. Several conditions are associated with RLS and include iron deficiency, pregnancy, and end-stage renal disease. Several medications and substances are known aggravators of RLS, including medications with antidopaminergic properties, such as metoclopramide and prochlorperazine. Nicotine, caffeine, and

alcohol can aggravate RLS through their own ability to interfere with quality of sleep. Additionally, SSRIs, TCAs, and commonly used over-the-counter antihistamines, such as diphenhydramine, can trigger or worsen RLS symptoms.[182] Hypotensive akathisia, leg cramps, and other conditions such as arthritis, which can cause positional discomfort with extended periods of sitting in one position, can mimic RLS. These conditions are easily distinguished from RLS because they are usually localized to certain joints or muscles, do not have a circadian pattern, and are not associated with an uncontrollable urge to move.

With an otherwise unremarkable physical examination and medical history, specific laboratory tests that should be performed in J.J. are limited to serum ferritin and percent transferrin saturation (total iron-binding capacity [TIBC]) to rule out iron deficiency anemia. Several studies have documented a relationship between low ferritin concentrations and increased symptom severity.[183] J.J. is postmenopausal, so a pregnancy test is not necessary. Polysomnography is not usually indicated unless there is clinical suspicion for sleep apnea or if sleep remains disrupted despite treatment of RLS. When clinical suspicion from the physical examination or medical history suggests a possible peripheral nerve or radiculopathy cause, a routine neurologic panel should be obtained.[182] In end-stage renal failure, screening for uremia should be considered because this can trigger symptoms.

Case 59-4, Question 2: What is the difference between RLS and PLMS?

In addition to the presence of RLS, the symptoms reported by the spouse of J.J. are likely related to PLMS. These are also known as nocturnal myoclonus and are best described as involuntary clonic-type movements of the lower extremities while sleeping that usually involve bilateral ankle dorsiflexion, knee flexion, and hip flexion. Approximately 80% of patients with RLS also have PLMS, but PLMS can occur by itself and is also associated with significant sleep dysfunction. The diagnosis of PLMS usually requires a

polysomnogram; the universally accepted criteria for diagnosis are that there should be at least four periodic leg movements (PLMs) in a 90-second period, with contractions typically lasting 0.5 to 5 seconds and recurring every 5 to 90 seconds.[184] A PLM index (PLMI) is calculated by dividing the total number of PLMs by sleep time in hours; an index of >5 but <25 is considered mild, a PMLI of >25 and <50 is moderate, and a PLMI of >50 is severe. The diagnosis of PLM disorder can be made when patients present with insomnia, tiredness, and daytime sleepiness in the presence of a high PLMI.[185] There is considerable overlap in the treatments of PLMS and RLS. Because J.J. clearly has RLS, there is no need to perform a polysomnogram. The diagnosis of PLMS in her case is incidental and would not alter the clinical management. An exception to this would be whether her medical history revealed the possibility of sleep apnea, because there is a high association between PLMS and upper airway resistance.[186]

Treatment

Case 59-4, Question 3: The decision is made to initiate drug therapy in J.J. for the management of her symptoms. What pharmacologic therapy should be selected? What nonpharmacologic therapies should be recommended?

It is important to rule out possible reversible causes before treating RLS. Three aspects should be considered including iron deficiency (defined as ferritin <75 ng/mL or iron/TIBC ratio <20%), medications, and lifestyle changes. Iron supplements can potentially cure RLS symptoms in patients found to be iron deficient.[188,189] If J.J. is iron deficient, she should be prescribed 50 to 65 mg of elemental iron one to three times daily on an empty stomach with 200 mg of vitamin C to enhance absorption. After ruling out possible reversible causes of RLS, it is important to establish the frequency of her symptoms and to select appropriate therapy.

Several classes of medications are effective for treating RLS.[183,187–189] Dopaminergic therapies are most consistently effective

in relieving RLS symptoms, improving sleep, and reducing leg movements. High-quality evidence has found that levodopa/carbidopa improves RLS symptoms.[183,188,189] Dopamine agonists are the preferred dopaminergic class to treat RLS because they are longer acting than levodopa, which allows for more sustained efficacy and control of symptoms throughout the entire night.[183,186,187] J.J. should be started on either ropinirole (0.25 mg initially, up to 0.5–4 mg/day) or pramipexole (0.125 mg initially, up to 0.5 mg/day) because both are FDA-approved for treating RLS. Although rotigotine is approved and supported by guidelines, the transdermal formulation may limit use in the early titration phases of RLS management.[57] Several randomized, controlled clinical trials have documented efficacy of these agents in both objective and subjective ratings of improvement by patients and clinicians with either short- or long-term use.[183,187–189] Ropinirole and pramipexole do not appear to differ with regard to efficacy or adverse effects. When used for RLS, ropinirole and pramipexole should be administered 2 hours before bedtime. Adverse effects are similar to those seen with the use of these agents in PD, and patients should be counseled accordingly.

Other medications may also provide benefit in RLS. Guidelines recommend the use of pregabalin and gabapentin enacarbil.[183,187–189] A recent double-blind study over 12 weeks compared the efficacy of pregabalin, pramipexole, and placebo, demonstrating a better efficacy of pregabalin rather than dopamine agonist or placebo.[190] Efficacy varied based on drug dosages. As a result of their mechanisms of action, these agents may be helpful if J.J. had RLS involving neuropathic pain or if she could not tolerate dopaminergic therapy. Although studied, there are inconclusive data to support the use of benzodiazepines, opiates (tramadol, methadone), anticonvulsants, clonidine, iron, folate, vitamin B_{12}, magnesium, vitamin E, and botulinum toxin.[183,187–189] Opiates may be helpful in patients who experience significant pain related to RLS, but these agents have not proven to conclusively treat RLS symptoms. Opiates are also associated with an increased risk of abuse potential

and should be avoided, especially along with benzodiazepines, alcohol, and other illicit drugs.[183,187,188,190] Risks associated with the use of opiates, including respiratory depression and addiction, should be reviewed with the patient prior to initiation. Benzodiazepines and opiates should be strongly avoided in concomitant sleep apnea because of their ability to suppress respiratory drive resulting in respiratory depression including death as well as abuse potential.

In addition to pharmacologic therapy, nonpharmacologic therapies and behavioral techniques should also be recommended for J.J. Most important among these include discontinuing all RLS aggravators (ie, sleep deprivation, alcohol or tobacco use, decreased mobility) and practicing good sleep hygiene. Physical and mental activity (eg, reading, playing card games, or working on the computer) if patients are unable to sleep can reduce symptoms.[182] Counter stimuli such as massage or hot baths may also be helpful.[182]

Case 59-4, Question 4: After carefully considering the costs of therapy, J.J. and her physician choose levodopa to treat her RLS instead of a dopamine agonist. She initially responds well to the therapy. One year later, J.J. returns for follow-up. Her dose of carbidopa/levodopa has progressively increased to three 25 mg/100 mg tablets at bedtime. She describes continued worsening of her symptoms that do not seem to be relieved with increasing doses of carbidopa/levodopa. Her symptoms are now starting earlier in the evening, occur almost every night, and are now painful. How should her therapy be further adjusted?

J.J. is likely experiencing augmentation, a common problem with long-term use of dopaminergic drugs, particularly levodopa.[191] Augmentation is described as a progressive worsening of RLS symptoms after an initial improvement and is manifested by gradually intensified symptoms that occur earlier in the evening and spread to other parts of the body.[192] It is the most common side effect occurring with long-term use (>3 months) of dopaminergic agents and usually occurs 6 to 18 months after therapy is initiated.[182] Doses of dopaminergic agents are often increased in response; however, with each incremental dose increase, symptoms progress

more rapidly until they may occur continuously throughout the day.[182] Although augmentation has been clinically recognized for many years, it has not been systematically studied. The exact etiology is uncertain, but it likely relates to the finding that RLS, unlike PD, is actually a hyperdopaminergic condition with an apparent postsynaptic desensitization that overcompensates during the circadian low point of dopaminergic activity in the evening and night. Adding dopamine in the evening initially corrects the symptoms, but ultimately leads to increasing postsynaptic desensitization.

The highest risk for augmentation is with levodopa. An estimated 50% to 85% of patients on levodopa will develop augmentation, compared with only 20% to 30% with dopamine agonists.[193] The primary treatment strategy for the management of augmentation is to withdraw the dopaminergic agent and substitute this with nondopaminergic agents. Given her presentation, J.J. should have her carbidopa/levodopa discontinued. She should be counseled that her symptoms will likely rebound severely for 48 to 72 hours, but ~4 to 7 days later, her symptoms should gradually return to baseline or pretreatment state.[182]

With the discontinuation of carbidopa/levodopa in J.J., an alternative therapy should be selected. The selection of an alternative agent in cases in which the initial therapy failed or augmentation occurs must be approached on an individual basis. Although a number of agents are available to choose from, clinical experience generally guides the decision because lack of comparative trials precludes development of any formal recommendations. Because J.J. describes increasing pain with her RLS, it would be appropriate to initiate a trial of gabapentin enacarbil or pregabalin. If ineffective or not tolerated, J.J. could be prescribed an opiate to manage her pain. Hydrocodone, oxycodone, methadone, codeine, and tramadol have all been evaluated in RLS.[182] Risks associated with opiate use, including respiratory depression and addiction, should be discussed in detail with J.J. prior to initiation. Augmentation does not prevent a future reintroduction of dopaminergic therapy; in the case of J.J., a dopamine agonist could be added after an extended dopaminergic

free period if her symptoms are not completely controlled with nondopaminergic agents or if her symptoms were not painful.

ESSENTIAL TREMOR

Clinical Presentation

CASE 59-5

QUESTION 1: K.H. is a 52-year-old White female office manager who was referred to a neurologist for evaluation of bilateral tremor. She is otherwise healthy and reports not taking any regularly prescribed medications. She describes her tremor as being present mainly when she performs voluntary movements. The tremor is not noticeable during rest. She also notices that the tremor seems to disappear in the evening after drinking a couple of glasses of wine. The tremor interferes with several of her ADLs, including writing, eating, drinking from a cup, and inserting her keys into the ignition. She reports mild interference with her job function and some social embarrassment. No bradykinesia or rigidity is elicited on physical examination. A handwriting sample reveals large characters that are difficult to decipher. Family history reveals that her maternal grandmother and mother both had similar symptoms.

What signs and symptoms are consistent with ET in K.H.?

Beginning in the mid-20th century, the term ET has been consistently used to describe a kinetic tremor for which no definite cause has been established. ET is a common neurologic disorder with an estimated incidence of 616 cases/100,000 person-years and a prevalence of about 0.9% to 4.6%.[194,195] Despite its prevalence, it is underrecognized and undertreated likely because it has been traditionally viewed as a monosymptomatic disorder of little consequence. More recently, it is recognized to be complex and progressive, which has resulted in significant disability in ADLs, job performance, and social embarrassment.[194] Both the incidence and prevalence of ET increase with age. Additionally, ethnicity and family history of ET are consistently identified risk factors. These risk factors are approximately five times more common in Whites than

Blacks, and ~50% of patients report a positive family history. The latter finding suggests that genetic predisposition may play a role in ET; however, differences in intrafamilial onset and severity suggest environmental factors may also influence underlying susceptibility to the disease. Several environmental toxins have been proposed as causes of ET, including β-carboline alkaloids (eg, harmane and harmine) and lead, both of which have been found in elevated concentrations in patients with ET compared with normal control subjects.[196–198]

Because parkinsonian tremor and ET are the most common forms of tremor observed in practice, it is important to distinguish between these two because the treatments differ substantially. Tremor should first be identified as either an action (ie, kinetic, postural, and isometric) or resting tremor. The defining feature of ET is a bilateral, largely symmetrical, 5- to 10-Hz kinetic and postural tremor of the arms. The tremor can also affect the head or voice. The symptoms must be present for >5 years and must not be attributable to other causes such as tremorogenic drugs.[197] Although both kinetic and postural action tremors can be present in ET and PD, the presence of resting tremor is much more common in PD. Lack of resting tremor and absence of bradykinesia or rigidity in K.H. suggests the tremor is not parkinsonian. She describes interference of her tremor occurring with voluntary movement such as with her ADLs and drinking from a cup. Other signs and symptoms that support a diagnosis of ET include her age, family history, large and tremulous handwriting (as opposed to micrographia in PD), and improvement in tremor with alcohol consumption. **Table 59-8** summarizes the similarities and differences of ET and parkinsonian tremor.

Table 59-8
Differentiation of Essential Tremor and Parkinson Disease

Characteristic	Essential Tremor	Parkinson Disease
Kinetic tremor areas frequently involved	Neck, voice	Mouth/ tongue, jaw, leg
Hemibody (arm and leg) tremor	0	++

Kinetic tremor > resting tremor	++	+
Resting tremor > kinetic tremor	0	++
Rigidity or bradykinesia	0	++
Postural instability	0	++
Usual age of onset (years)	15–25, 45–55	55–65
Symmetry	Bilateral	Unilateral > bilateral
Family history of tremor	+++	+
Response to alcohol	+++	0
Response to rest	+++	0
Response to activity	0	+++

Several medications and substances are known to cause tremor, and all patients should have thorough medication history to rule out these causes. Medications commonly implicated include corticosteroids, metoclopramide, valproate, sympathomimetics (eg, albuterol, amphetamines, pseudoephedrine), SSRIs, TCAs, theophylline, and thyroid preparations.[199,200] In addition, caffeine, tobacco, and chronic alcohol use can cause tremor that resembles ET. K.H. does not report taking any regularly prescribed medications; however, she should be questioned regarding any over-the-counter medication use as well as her alcohol use and caffeine and smoking habits.

The diagnosis of ET is based solely on clinical examination and neurologic history. Neuroimaging is not useful, and there are no available biologic markers or diagnostic tests that are specific to ET.

The evaluation of the tremor that K.H. is experiencing should include laboratory analysis to rule out possible medical conditions associated with tremor. Such conditions may include the presence of hyperthyroidism or Wilson disease (particularly in patients younger than 40 years of age).[199,200]

Treatment

Case 59-5, Question 2: What therapies are effective in treating ET? How should K.H. be treated?

Patients with ET who have a mild disability that does not cause functional impairment or social embarrassment can go without treatment. Because K.H. is experiencing tremor that is interfering with her occupation and causing social embarrassment, she should be considered for pharmacotherapy (**Table 59-9**). It is important to note that although effective treatments exist, tremor is rarely eliminated completely. Factors predicting lack of response have not been readily identified.

Table 59-9
Pharmacotherapy for Essential Tremor

Drug	Initial Dose	Usual Therapeutic Dose	Adverse Effects
β-Blockers			
Propranolol	10 mg every day to bid	120–320 mg divided every day to bid-tid; LA given once daily	Bradycardia, bronchospasm, fatigue, hypotension, lightheadedness, exercise intolerance, sexual dysfunction, depression
Atenolol	12.5–25 mg every day	50–150 mg every day	Bradycardia, fatigue, hypotension, exercise intolerance
Nadolol	40 mg every day	120–240 mg every day	Bradycardia, fatigue, hypotension, exercise intolerance
Anticonvulsants			
Gabapentin	300 mg every day in single or divided doses	1200–3600 mg divided tid	Nausea, drowsiness, dizziness, unsteadiness, weight gain, peripheral edema, potential for abuse
Pregabalin	75 mg bid	75–300 mg divided bid	Weight gain, dizziness, drowsiness, potential for abuse
Primidone	12.5 mg every day at bedtime	50–750 mg divided every day to tid	Sedation, fatigue, nausea, vomiting, malaise, ataxia, dizziness, confusion, vertigo
Topiramate	25 mg every day	150–400 mg divided bid	Appetite suppression, weight loss, paresthesias, concentration difficulties, nausea, fatigue, memory difficulties
Zonisamide	100 mg every day	225 mg divided doses	Headache, nausea, fatigue/sleepiness, diarrhea
Benzodiazepines			
Alprazolam	0.125 mg every day	0.75–3 mg divided tid	Sedation, fatigue, ataxia, dizziness, potential for misuse
Clonazepam	0.25 mg every day	0.5–2 mg divided every day to bid	Sedation, fatigue, ataxia, dizziness, impaired cognition, potential for misuse
Miscellaneous			
Botulinum toxin A	Varies by injection site: 50–100 units/arm for hand tremor; 40–400 units/neck for head tremor; 0.6–15 units/vocal cords for voice tremor; repeat no sooner than every 3 months (extend as long as possible)		Hand weakness (with wrist injection); dysphagia, hoarseness, breathiness (with neck or vocal cord injection)
Clozapine	12.5–25 mg every day	25–75 mg every day or divided every day to bid	Sedation, QT prolongation, orthostatic hypotension
Nimodipine	30 mg every day	120 mg every day	Hypotension, diarrhea, dyspepsia
Olanzapine	5 mg every day	10–20 mg every day or divided every day to bid	Weight gain, somnolence, extrapyramidal symptoms

bid, two times daily; tid, three times daily.

Propranolol, a nonselective β-adrenergic receptor blocker, or primidone, an anticonvulsant, are recommended as first-line agents to treat ET.[196,197] Propranolol is typically effective in doses of at least 120 mg/day with about 50% of patients having long-lasting benefit.[201] Long-acting propranolol is as effective as the regular-release formulation. Other β_1-selective blockers such as atenolol and metoprolol have also been studied but with mixed findings.[198,201,202] Propranolol has demonstrated greater efficacy than these β_1-selective agents, which suggests that blockade of β_2-receptors is of importance. β-Adrenergic receptor blockers with intrinsic sympathomimetic activity, such as pindolol, appear ineffective in ET.[198–202] Caution should be exercised with propranolol in patients with asthma, congestive heart failure, diabetes mellitus where signs

as well as symptoms of hypoglycemia can be masked, and atrioventricular block.

Several studies have compared propranolol and primidone in ET, and they are considered to have similar efficacy.[201–203] Primidone is metabolized to a phenobarbital-based metabolite; however, phenobarbital is inferior to primidone in treating ET.[203] Acute adverse effects of primidone include nausea, vomiting, and ataxia, which can occur in up to one-fourth of patients, often limiting its use.[201] A double-blind, comparative study showed that all doses were beneficial for ET; however, lower doses (250 mg) were as effective or better than higher dosages (750 mg).[204] Primidone should be initiated at 12.5 mg/day and administered at bedtime to reduce the occurrence of acute side effects. It can be titrated gradually as tolerated up to 750 mg/day in divided doses, although side effects become more common at doses >500 mg/day.[201]

Other agents that have demonstrated variable efficacy in ET include gabapentin, pregabalin, topiramate, zonisamide, clozapine, olanzapine, nimodipine, and benzodiazepines (specifically, alprazolam and clonazepam).[170–172] They are generally considered to be less-proven, second-line or third-line therapies. Adverse effects and potential for abuse should be considered when an agent is selected.

If oral pharmacotherapy options for ET are not beneficial, intramuscular injections of botulinum toxin A or surgical treatments can be used in selected patients.[170] Targeted botulinum toxin A injections can reduce hand, head, and voice tremor; however, they are associated with focal weakness of the adjacent areas.[169] Injections in the wrist can cause hand weakness, and dysphagia, hoarseness, and breathiness can occur with injections into the neck or vocal cords. The use of botulinum toxin injections in the United States is also limited by cost. Treatment should occur with the lowest dose, and the interval should be as long as possible between injections. DBS of the ventral intermediate nucleus of the thalamus or unilateral thalamotomy is possibly efficacious in reducing ET.[170] Greater improvement in self-reported measures of function and fewer adverse events make DBS the preferred surgical option of the

two.[170] Other therapies are being evaluated, including implantation in the caudal zona incerta (cZI) (alternative to ViM), lesional surgery (MRI-guided high-intensity focused ultrasound [MRIgFUS]) (less invasive than DBS), and perampanel.

Because K.H. is otherwise healthy, she is a good candidate for propranolol therapy. Propranolol can be initiated as needed or on a scheduled basis depending on the degree of impairment and desire of the patient. If the decision is made with K.H. to use propranolol on an as-needed basis, she should begin with one-half of a 20-mg tablet administered 30 minutes to 1 hour before the desired effect. The dose can be increased from one-half to two tablets. An example of a situation in which this may occur is whether she wants to avoid embarrassment with attending a social activity or before certain tasks requiring manual dexterity at work. Given the degree of her impairment, she is probably a better candidate for chronic suppressive therapy with propranolol. In this situation, she can be prescribed 10 mg twice daily, because it can be safely and easily uptitrated every few days to a minimally effective dose, generally not >120 to 360 mg/day in divided doses.

Seizure Disorders

Sulaiman Almohaish, Melissa Sandler, Nicole E. Omecene, and Gretchen M. Brophy

CORE PRINCIPLES		CHAPTER CASES
1	Epilepsy is a disorder characterized by spontaneously recurring seizures. Seizures can arise from a focal area of the brain (focal seizures) or arise diffusely from both brain hemispheres (primary generalized seizures).	**Case 60-1 (Question 1) Case 60-9 (Question 1)**
2	The optimal choice of antiseizure drug (ASD) treatment is based on patient-specific considerations, including seizure type (or epilepsy syndrome, if defined), age, sex, concomitant medical conditions and therapies, and ASD adverse effects. Monotherapy is preferred; polytherapy should be considered for patients with multiple seizure types and/or when monotherapy	**Case 60-1 (Question 2, 3) Case 60-3 (Question 1) Case 60-4 (Question 1) Case 60-6 (Question 1) Case 60-7 (Questions 1-6) Case 60-9 (Question 2,3)**

	(with two or three agents) fails at maximal tolerated doses.	
3	Standard ASDs, such as carbamazepine, phenytoin, and valproate, are used commonly for patients with newly diagnosed epilepsy. Newer ASDs (eg, lacosamide, lamotrigine, levetiracetam, oxcarbazepine, pregabalin, topiramate, zonisamide, perampanel, eslicarbazepine) are often initially approved for add-on therapy in patients with focal-onset seizures who do not respond to other ASDs. Lamotrigine, oxcarbazepine, topiramate, lacosamide, and felbamate are indicated for monotherapy.	**Case 60-1 (Question 3)** **Case 60-2 (Question 1-4)** **Case 60-6 (Question 1)**
4	Enzyme-inducing ASDs (carbamazepine, phenobarbital, phenytoin) increase the metabolism of many other drugs (eg, warfarin, contraceptive hormones). In addition, carbamazepine induces its own metabolism and its levels may decline during the first month of therapy despite excellent adherence.	**Case 60-1 (Question 5,6)** **Case 60-11 (Question 1)**
5	Serious idiosyncratic adverse effects have been associated with most standard and new ASDs and include carbamazepine-associated hematologic abnormalities; lamotrigine-associated skin rash; valproate-induced hepatotoxicity; and hypersensitivity	**Case 60-1 (Question 4)** **Case 60-2 (Question 1,3)** **Case 60-5 (Question 1)** **Case 60-7 (Questions 2, 8, 9)**

	syndrome seen with carbamazepine, phenobarbital, and phenytoin. The role of routine laboratory monitoring for the detection of these adverse effects is controversial. Patients should know the signs or symptoms that should prompt them to seek medical attention.	**Case 60-10 (Question 1, 2)** **Case 60-11 (Question 2)**
6	Unlike other ASDs, phenytoin displays capacity-limited pharmacokinetics at serum concentrations that are clinically useful for epilepsy treatment. As a consequence, phenytoin blood levels often change disproportionately to changes in dosage, and time to steady state varies significantly in individual patients based on the phenytoin concentration.	**Case 60-3 (Question 2, 3)**
7	Serum concentration monitoring can be useful for selected ASDs when there is a good correlation between concentration and therapeutic or toxic responses. However, clinical criteria (seizure control, medication tolerability) are the primary determinants of the need for dosage adjustments.	**Case 60-7 (Question 7)**
8	The occurrence of seizure clusters (acute repetitive seizures) and status epilepticus (SE; prolonged or repeated seizures without recovery of consciousness) warrants emergent ASD therapy. Acute repetitive seizures are often treated by parents or caregivers with rectal diazepam. SE is a life-	**Case 60-8 (Question 1)** **Case 60-12 (Question 1–4)**

threatening emergency and should be treated with intravenous (IV) lorazepam as initial therapy.

INTRODUCTION

Approximately 10% of the population will experience a seizure at some time in their life. Up to 30% of all seizures are provoked by central nervous system (CNS) disorders or insults (eg, meningitis, trauma, tumors, and exposure to toxins); these seizures may become recurrent and require chronic treatment with antiseizure drugs (ASDs). Reversible conditions such as alcohol withdrawal, fever, and metabolic disturbances may provoke acute, isolated seizures. These seizures, along with drug-induced seizures, are not considered to be epilepsy and usually do not require long-term ASD therapy. Approximately 1% of the general population has epilepsy.[1]

TERMINOLOGY, CLASSIFICATION, AND DIAGNOSIS OF EPILEPSIES

Classification of Seizures and Epilepsies

A seizure is the "transient occurrence of signs and/or symptoms because of abnormal excessive or synchronous neuronal activity in the brain."[2] These signs or symptoms "may include alterations of consciousness, motor, sensory, autonomic, or psychic events."[1] Epilepsy is a "disorder of the brain characterized by an enduring predisposition to generate epileptic seizures and by the neurobiologic, cognitive, psychological, and social consequence of this condition."[2] By definition, epilepsy requires the occurrence of two or more seizures that are not acutely provoked by other illnesses or conditions.[3] Guidelines have recently been updated to include a

patient who has had one unprovoked seizure and has a high risk (>60%) of a second seizure to be included in the definition of a person with epilepsy.[4]

Generalized Seizures

Tonic–clonic seizures affect both cerebral hemispheres. It is usually associated with loss of consciousness. In the initial tonic phase, sudden muscle spasms begin and may be accompanied by a cry that results from air being forced through the larynx. This tonic phase is followed by a clonic phase characterized by symmetric twitching movements of the bilateral muscles. After the clonic phase, patients return to consciousness but may remain lethargic and may be confused for varying periods of time (postictal state). Urinary incontinence and tongue biting are common. Primary generalized tonic–clonic seizures affect both cerebral hemispheres from the outset. Secondary generalized tonic–clonic seizures begin as focal seizures. The aura described by some patients before a generalized tonic–clonic seizure represents an initial focal seizure that spreads to become a secondary generalized seizure. Identification of secondary generalized tonic–clonic seizures is important because some ASDs are more effective at controlling primary generalized seizures than secondary generalized seizures. In general, focal seizures are often more difficult to control with ASDs as compared to primary generalized seizures. Other types of generalized seizures include myoclonic seizures (asymmetric twitching movements of muscles), clonic seizures, tonic seizures, and atonic seizures.[3,5–7]

Nonmotor/absence seizures occur primarily in children and often remit during puberty; affected patients may exhibit a second type of seizure. Absence seizures consist of a brief loss of consciousness, usually lasting several seconds. Typical absence seizures are not accompanied by motor symptoms; automatisms, muscle twitching, myoclonic jerking, or autonomic manifestations may accompany atypical absence seizures. Other types of absence seizures include myoclonic absence and eyelid myoclonia.[3,5–8]

Patients are unaware of their surroundings and will have no recall of events during the seizure. Consciousness returns immediately when the seizure ends, and postictal confusion does not occur. Differentiation of atypical absence seizures from complex partial seizures may be difficult if only a second-hand account of the episodes is available; identification of a focal abnormality by an electroencephalogram (EEG) often is necessary to identify complex partial seizures. This distinction is important for the proper selection of an ASD.

Focal Seizures

Focal seizures without impairment of consciousness, previously called simple partial seizures, are localized in a single cerebral hemisphere or portion of a hemisphere. Consciousness is not impaired during these events. Various motor, sensory, or psychic manifestations may occur depending on the area of the brain that is affected. A single part of the body may twitch, or the patient may experience only an unusual sensory experience.[7,8]

Focal seizures with impairment of consciousness or “dyscognitive features,” previously called complex partial seizures, result from the spread of focal discharges to involve a larger area. Consciousness is impaired and patients may exhibit complex but inappropriate behavior (automatisms), such as lip smacking, picking at clothing, or aimless wandering. A period of brief postictal lethargy or confusion is common.[7,8]

Focal seizures that evolve to generalized seizures (secondary generalized seizure) include one or both types of focal seizures that evolve to generalized seizures.[7,8]

Epilepsy Syndromes

Epilepsy syndromes can be defined on the basis of seizure type as well as cause (if known), precipitating factors, age of onset, characteristic EEG patterns, severity, chronicity, family history, and

prognosis. Accurate diagnosis of epilepsy syndromes may better guide clinicians regarding the need for drug therapy, the choice of appropriate medication, and the likelihood of successful treatment.[1,5,6] Many epilepsy syndromes have been defined; a complete listing is beyond the scope of this chapter. Several are of interest with respect to pharmacotherapy. Some examples are described in **Table 60-1**.[6]

Table 60-1
Examples of Epilepsy Syndromes and Associated Pharmacotherapy

Syndrome	Seizure Patterns and Characteristics	Preferred ASD Therapy	Comments
Juvenile myoclonic epilepsy	Myoclonic seizures often precede generalized tonic–clonic seizures Sleep deprivation, photosensitivity, and excess alcohol consumption commonly precipitate seizures	Valproate Levetiracetam FDA approved as an adjunct for myoclonic seizures Lamotrigine and levetiracetam preferred in patients of childbearing potential Topiramate and zonisamide may also be effective	5%–10% of all epilepsies; 85%–90% response to valproate Lifelong therapy usually needed High relapse rate with attempts to discontinue ASD therapy
Lennox–Gastaut syndrome	Generalized, atypical absence, atonic/akinetic, myoclonic, and tonic seizures most common Often accompanied by cognitive dysfunction and mental retardation	Valproate and benzodiazepines may be effective Lamotrigine, rufinamide, topiramate, cannabidiol, and clobazam FDA-approved Felbamate may be effective, but potential hematologic toxicity limits use	Poorly responsive to ASD therapy and requires multiple agents for control Oversedation with aggressive treatment strategies may increase seizure frequency Tolerance to benzodiazepines limits their usefulness
Childhood absence epilepsy	Typical absence seizures often present in clusters Tonic–clonic seizures occur in ~40% Onset usually between ages 4 and 8 years and disappears by adolescence Significant genetic component	Ethosuximide or valproate Lamotrigine less effective	80%–90% response rate to ASD therapy Good prognosis for remission Tonic–clonic seizures may persist

ASD, antiseizure drug; FDA, U.S. Food and Drug Administration.

DIAGNOSIS

Optimal treatment of seizure disorders requires accurate classification (diagnosis) of seizure type and appropriate choice and use of medications. Seizure classification may be straightforward if an adequate history and description of the clinical seizure are available. Physicians often do not observe patients' seizures; thus,

family members, teachers, nurses, and others who have frequent direct contact with patients should learn to objectively describe and record these events. The onset, duration, and characteristics of a seizure should be described as completely as possible. Several aspects of the events surrounding a seizure may be especially significant: the patient's behavior before the seizure (eg, Did the patient report feeling ill or describe an unusual sensation?), deviation of the eyes or head to one side or localization of convulsive activity to one portion of the body, impaired consciousness, loss of continence, and the patient's behavior after the seizure (eg, Was there any postictal confusion?). In addition, it is helpful if the observer can record the length of the event and how long it took for the patient to return to baseline. A video of the event could be especially helpful. The patient and caregivers should have a seizure calendar or diary to record events. Many options exist to track seizures including online sites and smartphone applications. Those who observe a seizure should not try to label the seizure but should be encouraged to describe the event fully and objectively.

Accurate seizure diagnosis and identification of the type of epilepsy or epilepsy syndrome also depend on neurologic examination, medical history, and diagnostic techniques, such as EEG, computed tomography (CT), and magnetic resonance imaging (MRI). The EEG often is critical for identifying specific seizure types. CT scanning may help assess newly diagnosed patients, but MRI is preferred. MRI may locate brain lesions or anatomic defects that are missed by conventional radiographs or CT scans.[9]

CASE 60-1

QUESTION 1: A.R. is a 14-year-old, 88.18-pound (40-kg) female high school student. A.R. had three complex febrile seizures when she was 3 years old. According to her parents, she received phenobarbital prophylaxis "off and on," for about 6 months after her second febrile seizure. Since then, she had no reported seizures until 24 hours before admission. At that time, she had a "convulsion" shortly after arriving at school in the morning. A teacher who witnessed the episode describes her as behaving "oddly" before the seizure. She abruptly got up from her desk and began to walk clumsily toward the door;

she bumped into several desks and did not respond to the teacher's attempts to redirect her back to her seat. After ~1 minute of this behavior, she fell to the floor and experienced an apparent generalized tonic–clonic seizure that lasted ~90 seconds. During the episode, she was incontinent of urine and was described as "turning kind of blue." After this episode, A.R. was transported to the hospital.

On arrival at the hospital, A.R. appeared drowsy and confused. Laboratory studies—a complete blood count (CBC), serum glucose, electrolytes, drug and alcohol screen, and lumbar puncture—were normal. Physical examination and a complete neurologic evaluation were normal. An EEG showed diffuse slowing with focal epileptiform discharges in the left temporal area; it was interpreted as abnormal. There was no history of recent illness or injury, although A.R. had stayed up late several nights recently studying for an examination.

A second seizure occurred in the hospital. The nursing staff described an episode similar to the one that occurred at school. After recovery from each episode, A.R. had no memory of events during the seizures; she only remembered a "funny feeling" in her stomach and a "buzzing" in her head before she lost consciousness. She described having these feelings "a couple of times" in the past; she attributed them to "just getting dizzy" and had not reported them to her parents. After these previous episodes, A.R. described feeling confused and groggy for a few minutes.

What subjective and objective features of A.R.'s seizures are consistent with a diagnosis of focal impaired awareness seizures with secondary generalization?

A.R.'s clinical pattern of observed seizure activity (an apparent aura preceding her loss of consciousness), her history of apparent focal seizures not accompanied by generalized seizures, and the findings of focal abnormal activity on EEG are all concordant with this diagnosis. Postictal confusion and grogginess are common after both generalized tonic–clonic and focal seizures. Her unusual or inappropriate behavior represents a focal seizure that subsequently generalized. The clinical features, accompanied by her EEG findings, also help rule out possible atypical absence seizures, which can be confused with focal epilepsy syndromes if based on clinical presentation alone. In both syndromes, patients may briefly appear to lose contact with their surroundings and display automatisms and mild clonic movements during seizure activity. In A.R.'s case, the EEG and the generalized tonic–clonic seizures during her episodes would rule out atypical absence as a likely possibility.

TREATMENT

Early control of epileptic seizures is important because it allows normalization of patients' lives and prevents acute physical harm and long-term morbidity associated with recurrent seizures. In addition, early control of tonic–clonic seizures is associated with a reduced likelihood of seizure recurrence. Early control of epileptic seizures also correlates with successful discontinuation of ASD treatment after long-term seizure control.[10–12]

Nonpharmacologic Treatment of Epilepsy

Caregivers, teachers, and nurses should be familiar with recommendations for providing first aid to a person experiencing a seizure. These steps include the following: (a) remain with the person until they recover and time and record the seizure; (b) move any close objects away to ensure safety; (c) if unconscious, turn the person on their side, maintain a clear airway, and secure their head; (d) if available, give the person their rescue medication; (e) do not put any objects in their mouth; and (f) call emergency providers if a seizure lasts longer than 5 minutes, the person is mentally altered after the episode, or if the person develops any difficulty in breathing.[13]

Alternatives or adjuncts to pharmacotherapy may be helpful in some patients. Surgery is an extremely effective treatment in selected patients. Depending on the epilepsy syndrome and procedure performed, up to 90% of patients treated surgically may improve or become seizure-free. A study of 80 patients with medically refractory temporal lobe epilepsy randomly assigned to either surgery or continued medical treatment showed that, after 1 year, patients were more likely to be seizure-free after surgery.[14] Surgery is advocated as early therapy for some patients with specific epilepsy syndromes, such as mesial temporal sclerosis. Early surgical intervention may prevent or lessen neurologic deterioration and developmental delay.

Dietary modification may be used for patients who cannot tolerate ASDs or to treat seizures that are not completely responsive to ASDs. In most circumstances, dietary modification consists of a ketogenic diet. This low-carbohydrate, high-fat diet results in persistent ketosis, which is believed to play a major role in the therapeutic effect. Evaluation of the amount of carbohydrates patients receive from their medications while on ketogenic diets is also very important. Ketogenic diets seem to be most beneficial in children; they are also used as an adjunct to ongoing ASD treatment.[15,16]

The vagus nerve stimulator is an implantable device approved for the treatment of intractable focal seizures. This device uses electrodes attached around the left branch of the vagus nerve. The electrodes are attached to a programmable stimulator that delivers stimuli on a regular cycling basis; patients can also use “on-demand” stimulation at the onset of seizures by swiping the magnet over the subcutaneously implanted stimulator. Approximately 30% to 40% of patients who are so treated have a positive response (50% reduction in seizures).[17] The primary adverse effect of this device is hoarseness during stimulation; infrequently, this is accompanied by left vocal cord paralysis.

Responsive neurostimulation (RNS) is a newer nonpharmacologic option for treating intractable focal seizures and for patients who are not surgical candidates. This implantable device acts like a heart pacemaker as it can monitor abnormal brain activity and provide on-demand small electrical impulses to reduce seizures. One study found the risk of sudden unexpected death in epilepsy (SUDEP) was significantly reduced when using RNS.[18] It also appears to be safe with low cognitive adverse events and low risk for bleeding or infection as compared to other neurosurgical procedures.[19] However, its exact role in therapy is yet to be determined as some patients respond to treatment better than others and efficacy improves over time.

AVOIDANCE OF POTENTIAL SEIZURE PRECIPITANTS

It is impossible to generalize about environmental and lifestyle precipitants of seizure activity in persons with epilepsy. Individual patients or caregivers may identify specific circumstances such as stress, sleep deprivation, acute illness, or ingestion of excessive amounts of caffeine or alcohol, which may increase the likelihood of a recurrent seizure event. Individuals may experience an increase in the frequency and/or severity of seizures around the time of menstruation or ovulation. Patients with epilepsy should avoid activities that seem to precipitate seizures; as always, the goal is complete seizure control with as little alteration in the quality of life as possible.

Antiseizure Drug Therapy

Pharmacotherapy is the mainstay of treatment for epilepsy. Therefore, patient education regarding medications and consultation among health care professionals regarding the optimal use of ASDs are essential to quality patient care. Optimal ASD therapy completely controls seizures in approximately two-thirds of patients.[20,21] Optimization of drug therapy depends on several factors, with the choice of appropriate ASD, individualization of dosing, and adherence being the most important.

CHOICE OF ANTISEIZURE DRUG

Many ASDs have a relatively narrow spectrum of efficacy against selected seizure types; therefore, the choice of appropriate drug therapy for a specific patient depends on an accurate diagnosis of epilepsy. In addition, toxicity must be considered when selecting an ASD. Preferred drugs for specific types of seizures and common epileptic syndromes are listed in **Tables 60-2** and **60-3**. Although certain drugs are preferred, the identification of the most effective drug for a particular patient may be a process of trial and error; several medication trials may be necessary before success is achieved. It is important to keep in mind that certain ASDs can worsen seizures.[22]

Table 60-2
Antiseizure Drugs Useful for Various Seizure Types

Primary Generalized Tonic–Clonic	Secondary Generalized Tonic–Clonic	Focal—With or Without Awareness	Absence	Myoclonic, Atonic/Akinetic
Most Effective with Least Toxicity[a]				
Valproate	Carbamazepine	Carbamazepine	Ethosuximide	Valproate
Levetiracetam	Oxcarbazepine	Oxcarbazepine	Valproate	Clonazepam
Lamotrigine	Levetiracetam	Levetiracetam or brivaracetam	Lamotrigine	Rufinamide (Lennox–Gastaut syndrome)
(Oxcarbazepine)	Lamotrigine	Lamotrigine	Topiramate	Levetiracetam (juvenile myoclonic epilepsy)
Perampanel	Valproate	Valproate		Lamotrigine
	Gabapentin	Gabapentin		Clobazam (Lennox–Gastaut syndrome)
	Topiramate	Cenobamate		Topiramate
	Tiagabine Zonisamide Pregabalin Lacosamide Perampanel Eslicarbazepine	Topiramate Tiagabine Pregabalin Zonisamide Lacosamide Perampanel Eslicarbazepine		
Effective, but Often Poorly Tolerated or Cause Unacceptable Toxicity				
Phenobarbital	Phenobarbital	Clorazepate	Clonazepam	Felbamate[b]
Primidone	Primidone	Phenobarbital		
Felbamate[b]	Felbamate[b]	Primidone		
Phenytoin	Phenytoin Vigabatrin[c]	Felbamate[b] Phenytoin Vigabatrin[c]		

[a]Drugs are listed in general order of preference within each category. Recommendations by various authorities may differ. The use of phenobarbital and primidone is discouraged.

[b]Felbamate is placed on this table only to indicate the types of seizures for which it appears to be effective. Felbamate has been associated with aplastic anemia and hepatic failure; until a possible causative role is clarified, felbamate cannot be recommended for treatment of epilepsy unless all other, potentially less toxic, treatment options have been exhausted.

[c]Vigabatrin causes progressive and permanent visual field constriction that is related to total dose and duration of exposure. Vigabatrin cannot be recommended for treatment of epilepsy unless other potentially less toxic treatment options have been exhausted.

The consensus method was used to analyze expert opinion on the treatment of three epilepsy syndromes and status epilepticus (SE).[23] The experts recommended monotherapy first, followed by a second monotherapy agent if the first failed. If the second monotherapy failed, the experts were not in agreement on whether to try a third monotherapy agent or to combine two therapies. The experts

recommended epilepsy surgery evaluation after the third failed ASD for patients with symptomatic localization-related epilepsies.

To assess the evidence on efficacy, tolerability, and safety of many of the new ASDs in treating children and adults with new-onset and refractory focal and generalized epilepsies, a panel evaluated the available evidence.[24,25] They concluded that ASD choice depends on seizure and syndrome type; patient age; concomitant medications; and ASD tolerability, safety, and efficacy. The results of these two evidence-based assessments provide guidelines for the use of newer ASDs in patients with new-onset and refractory epilepsy.

THERAPEUTIC END POINTS

The individual patient's response to ASD treatment (ie, seizure frequency and severity and symptoms of toxicity) must be the major focus for therapy assessment. In general, the goal of ASD treatment is the administration of sufficient medication to completely prevent seizures without producing significant toxicity.[26] Realistically, this goal may be compromised for many patients; it may not be possible to completely prevent seizures without producing intolerable adverse effects. Thus, the therapeutic end points achieved can vary among patients; optimization of ASD therapy for a specific person depends on tailoring therapy to the patient's needs and lifestyle. It is rarely optimal to administer "standard" or "usual" doses of an ASD to a patient or to adjust doses to achieve a "therapeutic blood level" without considering the effect of the dose or serum concentration on the patient's condition and quality of life. As with many conditions requiring chronic drug therapy, patient participation in developing and evaluating a therapeutic plan is extremely important. Patients should be educated regarding the expected positive and negative effects of their ASD therapy, and they must be encouraged to communicate with their health care provider regarding their responses to prescribed ASDs.

CASE 60-1, QUESTION 2: What factors should be considered in a decision to treat A.R.'s seizures with scheduled ASD therapy?

Once a diagnosis of epilepsy is established, the decision to treat the patient with medication is based on the likelihood of recurrence. The need for ASD therapy after a single seizure is controversial. Evidence-based guidelines for adults and children generally state that the risk of recurrence is greatest within the first two years after the initial seizure occurrence and depends on etiology and EEG status.[4,27]

In A.R.'s case, the seizures experienced in the past 24 hours count as an initial unprovoked seizure. She experienced focal seizures, and some were followed by secondary generalized tonic–clonic seizures. Recurrence of seizure activity is likely to result in physical injury, social embarrassment, and interference with her participation in activities typical of a person her age. If her seizures are not controlled, she faces future limitation of her driving privileges and may face barriers to employment. A.R. also has a baseline risk of epilepsy given her history of complex febrile seizures. The potential benefits of immediate introduction of ASD therapy appear to outweigh potential associated risks.

SERUM DRUG CONCENTRATIONS

Relation to clinical response

For selected ASDs, proper use and interpretation of serum concentrations are important for optimizing treatment regimens in epilepsy.[28,29] An individual patient's clinical response to ASD treatment must be the major focus for therapy assessment. Individual patients often differ dramatically in their response to a particular serum drug concentration; therefore, therapeutic serum concentrations should be considered only as guidelines for treatment. Many patients' condition may be controlled with serum drug concentrations above or below the usual therapeutic range.[30] In these patients, dosage adjustment to get the patient "in range" is not warranted. It is better to "treat the patient, not the level."

Interestingly, a recent Cochrane Review found no evidence that measuring ASD concentrations routinely to inform dose adjustments is superior to dose adjustments based on clinical information.[31]

However, the authors do state that their review does not exclude the possibility that ASD serum concentration might be useful in special situations or in selected patients.

Indications for use

Measurement of serum drug concentrations may provide clinically useful information in the following situations:

- Uncontrolled seizures despite administration of greater-than-average doses: Serum concentrations of ASD may help distinguish drug resistance from subtherapeutic drug concentrations caused by malabsorption, nonadherence, or rapid metabolism.
- Seizure recurrence in a patient whose seizures were previously controlled: This is often owing to nonadherence to the prescribed medication regimen.
- Documentation of intoxication: In patients who exhibit signs or symptoms of dose-related ASD toxicity, documentation of the dose and serum concentration of the responsible drug is helpful.
- Assessment of patient adherence: Although monitoring ASD serum concentrations can be used to assess patient adherence to therapy, conclusions must be based on comparisons with previous steady-state serum concentrations that reflected reliable intake of a given dose of ASD.
- Documentation of desired results from a dose change or other therapeutic maneuver (eg, administration of a loading dose): When patients are receiving multiple ASDs, it is often appropriate to measure serum concentrations of all drugs after a change in the dose of one agent because changes to one drug frequently affect the pharmacokinetic disposition of other drugs.
- When precise dosage changes are required: On occasion, small changes in the dose of a drug (eg, phenytoin) can result in large changes in both the serum concentration and clinical response. In addition, cautious titration of dosage and serum concentration may be necessary to avoid intoxication. Knowledge of the serum drug

concentration before the dosage change may allow the clinician to select a more appropriate new maintenance dose.

- During pregnancy, ASDs serum concentrations often decline, and dosage adjustments may be warranted to maintain adequate seizure protection. Free (unbound) concentrations should be monitored for highly protein-bound ASDs (eg, phenytoin and valproate). ASD serum concentrations should be monitored after delivery, particularly when dosage escalations have been made during pregnancy.

Frequent, "routine" determinations of serum ASD concentrations are costly and not warranted for patients whose clinical status is stable. Clinicians may tend to focus attention on normal variability in serum concentrations rather than on the patient's clinical status; as a result, unnecessary dosage adjustments may be made to make serum concentrations fit the "normal range." A plan of action for what the clinician is going to do with the information once it is obtained should be in place before obtaining the sample. Therefore, the results of individual serum concentration determinations must be evaluated carefully to decide whether a significant, clinically meaningful change has occurred.[32]

Interpretation of serum concentrations

Several factors can alter the relationship between ASD serum concentration and the patient's response to the drug. Whenever a change in serum concentration is apparent, pharmacokinetic factors (see Table 60-3) should be considered (along with the patient's clinical status) before a decision is made to adjust the ASD dosage. Laboratory variability can cause minor fluctuations in reported ASD serum concentrations. Under the best conditions, reported values for serum concentrations may be within 10% of "true" values.[33,34] Therefore, the magnitude of any apparent change must be considered. Published therapeutic ranges may have been determined in small numbers of patients or may more accurately represent average serum concentrations at usual doses. Inappropriate sample timing can result in inconsistent and clinically

meaningless changes in ASD serum concentrations.[28] Generally, serum concentrations of ASD should not be measured until a minimum of four to five half-lives have elapsed since initiation of therapy or a dosage change. Blood samples should be obtained in the morning, before any doses of the ASD have been taken; this practice provides reproducible, postabsorptive (ie, “trough”) serum concentrations. Binding to serum proteins is significant for some ASDs (eg, phenytoin, valproate, tiagabine). Changes in protein binding can result from drug interaction, renal failure, pregnancy, or changes in nutritional status. These changes can alter the usual relationship between the measured total drug concentration (bound and unbound to plasma proteins) and the unbound (pharmacologically active) drug concentration. This change may not be apparent when only total serum concentrations are measured. Determination of serum concentrations of free (ie, unbound) ASDs is available from many commercial laboratories; these determinations are expensive, and results may not be available for several days. If significant changes in protein binding are suspected, measurement of free concentrations of ASD may provide additional information useful for adjustment of doses or interpretation of the patient’s symptoms.[23,34,35]

Table 60-3
Pharmacokinetic Properties of Antiseizure Drugs

Drug	Oral Absorption (%)	Half-Life (hours)	Time to Steady State[a]	Usual Therapeutic Serum Concentration	Plasma Protein Binding (%)	Volume of Distribution (L/kg)
Brivaracetam	NA	9	2–3 days	Not determined	<20	0.5
Cannabidiol	NA	56–61	9–10 days	Not determined	>94	NA
Carbamazepine	90–100	*Chronic:* 5–25	2–4 days	5–12 μg/mL	75 (50–90)	0.8–1.6

NA, not available; VPA, valproic acid.

[a]Based on four half-lives. This lag time should allow determination of steady-state serum concentrations within the limits of most assay sensitivities.

MONOTHERAPY VERSUS POLYTHERAPY

Evaluation of the effectiveness of polytherapy has shown little advantage for most patients. Use of a single drug at optimal tolerated serum concentrations produces excellent therapeutic results and minimal adverse effects in most patients. Addition of a second ASD significantly improves seizure control in only 10% to 20% of patients.[36,37] Reduction or elimination of existing polytherapy in patients with longstanding seizure disorders often lessens or eliminates cognitive impairment and other adverse effects; seizure control actually may improve.[36,38–41]

Most experts advocate the use of a single ASD (monotherapy) whenever possible. Successful monotherapy may require higher-than-usual ASD doses or serum concentrations greater than the upper limit of the usual therapeutic range.[42,43] Addition of a second

drug may be necessary in some patients; however, polytherapy should be reserved for patients with multiple seizure types or for patients in whom first-line ASDs have failed to control seizures when titrated to maximal tolerated doses.[23,39,42] When a new ASD is added to a patient's regimen with the goal of improving seizure control, the existing ASD regimen should be scrutinized for continued value. In some cases, a patient's ASD regimen can accumulate drugs that may be unnecessary because they were started and never re-evaluated. Continued vigilance and critical assessment of every drug in a patient's regimen is important.

Use of polytherapy creates several disadvantages that must be weighed against possible benefits. Seizure control may not significantly improve. Health care costs, for medications and for increased laboratory monitoring, may increase significantly with polytherapy. In addition, drug interactions among ASDs can complicate assessment of the patient's response and serum concentrations. Patient adherence often is worsened when multiple medications are prescribed, and adverse effects often increase.

Although ASD monotherapy is preferred whenever feasible, the recent introduction of several new ASDs has increased the use of polytherapy.[43]

DURATION OF THERAPY AND DISCONTINUATION OF ANTISEIZURE DRUGS

A diagnosis of epilepsy may not necessitate lifelong drug therapy. Several long-term studies have shown that ASD therapy may be successfully withdrawn from some patients after a seizure-free period of 2 to 5 years.[10–12] Seizures recurred in only 12% to 36% of patients who were followed for up to 23 years after ASD withdrawal. Therefore, many patients whose epilepsy is completely controlled with medication can stop therapy after a seizure-free period of at least 2 years.

Discontinuation of medications is advantageous for economic, medical, and psychosocial reasons. Costs associated with health care visits, serum concentration determinations, and the medications

themselves are eliminated or reduced. The risk of adverse effects from long-term medication use is eliminated, and patients can expect fewer lifestyle restrictions. Attempts to withdraw ASD therapy are associated with risks, however. Primary among them is the reappearance of seizure activity, which can result in SE, loss of driving privileges, employment difficulties, and/or physical injury.

Risk factors for seizure recurrence after discontinuation of ASD have been identified in observational studies; complete agreement, however, is not found among studies regarding the nature and importance of specific risk factors (**Table 60-4**). Opinions and data also differ regarding the optimal duration of the seizure-free period before discontinuation of ASD is attempted.[10,12,44,45]

Table 60-4

Risk Factors Possibly Predicting Seizure Recurrence After Antiseizure Drug Withdrawal

- <2 years seizure-free before withdrawal
- Onset of seizures after age 12
- History of atypical febrile seizures
- Family history of seizures
- 2–6 years before seizures controlled
- Large number of seizures (>30) before control or total of >100 seizures
- Focal seizures (with or without impaired awareness)
- Abnormal EEG persisting throughout treatment
- Slowing on EEG before medication withdrawal
- Organic neurologic disorder
- Moderate-to-severe mental retardation

EEG, electroencephalogram.

In nonemergency situations, ASD should be withdrawn slowly; if a patient receives multiple drugs, each drug should be withdrawn separately. Too-rapid withdrawal can result in SE. Clinical studies of ASD discontinuation usually used a 2- to 3-month withdrawal schedule for each drug. The optimal rate of withdrawal of ASD has not been identified. One study compared withdrawal of individual drugs for a 6-week and a 9-month period and found no difference in

seizure recurrence between the groups.[46] Another study compared seizure frequencies in patients withdrawn from carbamazepine rapidly (for 4 days) and in patients withdrawn more slowly (for 10 days).[47] Significantly more generalized tonic–clonic seizures occurred when carbamazepine was withdrawn rapidly; focal impaired awareness seizures, however, did not occur at a higher rate with rapid withdrawal. Therefore, withdrawal of each ASD for at least 6 weeks would seem to be a safe approach. Gradual withdrawal is recommended even for medications such as phenobarbital that have long half-lives and should theoretically be "self-tapering." In our experience, gradual reduction of medications such as phenobarbital is associated with a significantly higher success rate. If ASDs are withdrawn at an appropriate rate and seizures recur, drug treatment is usually reinstituted. In most patients, good seizure control is regained by restarting therapy. However, ~1% of patients had recurrent seizures that could not be controlled again with ASDs.[48] This uncommon, but potentially serious, the outcome should be considered when therapy withdrawal is considered.

CLINICAL ASSESSMENT AND TREATMENT OF EPILEPSY

Choice of Antiseizure Drug

CASE 60-1, QUESTION 3: Which ASDs are commonly used for A.R.'s seizure type?

Based on the subjective and objective data available, recommend a first-line ASD for A.R. and a plan for initial dosing of this medication.

Many ASDs would be appropriate choices for A.R.'s focal seizures with secondary generalized seizures (see **Table 60-2**).[37,49,50] Although valproate is effective for treating both generalized and focal

seizures,[51] it would not be a good initial choice for this patient owing to the risk of teratogenicity in a patient of childbearing age (see Other Therapeutic Considerations section).

Cenobamate, eslicarbazepine, felbamate, gabapentin, lacosamide, lamotrigine, levetiracetam, oxcarbazepine, perampanel, pregabalin, tiagabine, topiramate, carbamazepine, and zonisamide are effective for control of focal seizures with or without secondary generalization. Most experience with these drugs was obtained when they were used as adjunctive agents when previous ASD therapies were unsuccessful. Initial clinical trials with these medications indicate that several of them may be useful as single agents. Cenobamate, felbamate, lacosamide, lamotrigine, oxcarbazepine, carbamazepine, and topiramate have monotherapy indications. These medications appear to be safe and are usually well tolerated. The usefulness of felbamate is limited, however, owing to its potential for serious hematologic and hepatic toxicity.

Carbamazepine has several advantages that make it a reasonable first-line agent. Compared with other agents, carbamazepine is less sedating and is not associated with adverse effects such as hirsutism, acne, gingival hyperplasia, and coarsening of facial features. Although typical dosing generally requires multiple daily doses, there are extended-release formulations available to minimize the frequency of administration. In A.R.'s case, the lack of cosmetic adverse effects may be especially significant because she may be taking medication for many years. In addition, reduced sedation may be important with respect to her school performance.

Carbamazepine Therapy

INITIATION AND DOSAGE

It is recommended to screen the patients of Asian ancestry for HLA-B*15:02 allele prior starting carbamazepine therapy to avoid life-threatening adverse events such as Stevens–Johnson syndrome or toxic epidermal necrolysis. Initiation of treatment with full therapeutic maintenance doses of carbamazepine often causes excessive

adverse effects such as nausea, vomiting, diplopia, and significant sedation. Therefore, carbamazepine therapy should be gradually increased over time. Final dosing requirements are difficult to anticipate in individual patients. A reasonable starting dosage of carbamazepine for A.R. would be 100 mg twice a day; her dosage could be increased by 100 to 200 mg/day every 7 to 14 days. The titration schedule will depend on A.R.'s tolerance for the drug and the frequency of her seizures.

CASE 60-1, QUESTION 4: Carbamazepine has been associated with hematologic and hepatic toxicities. What is the incidence and significance of these toxicities? How should A.R. be monitored for them?

HEMATOLOGIC TOXICITY

Aplastic anemia and agranulocytosis have occurred in association with carbamazepine therapy.[52] Several cases have been fatal; however, most cases occurred in older patients treated for trigeminal neuralgia. Many patients were receiving other medications, and occasionally the reports were incomplete; thus, causal relationship for carbamazepine is difficult to assess.[53] Blood dyscrasias from carbamazepine seem rare (estimated prevalence <1/50,000) and have predominantly occurred in patients without epilepsy. Data in case series and clinical trials of carbamazepine therapy in patients with epilepsy do not report severe hematologic toxicity.[54,55]

Leukopenia is relatively common in patients taking carbamazepine. It is usually mild and often resolves without discontinuation of the drug.[54] Total leukocyte counts may fall to <4,000 cells/μL in some patients, but differentials and platelet and erythrocyte counts remain normal. Symptoms (eg, fever, sore throat) that might suggest early stages of agranulocytosis do not occur. Carbamazepine-associated hematologic disorders are not generally dose related.

Routine hematologic testing

Laboratory monitoring of A.R.'s hematologic status is recommended before and during carbamazepine therapy. Hematologic toxicity from carbamazepine typically occurring early in therapy monitoring does not appear to provide a benefit in the detection of aplastic anemia or agranulocytosis.[54,56] Therefore, baseline and monthly CBCs are advised for the first 3 months of therapy. Thereafter, A.R. should have a yearly CBC with differential.

HEPATOTOXICITY

Carbamazepine-related liver damage is extremely rare despite warnings in the package insert.[57,58] Hepatotoxicity from carbamazepine is believed to be idiosyncratic or immunologically based. Aggressive laboratory monitoring of liver function tests (LFTs) probably is unnecessary.[56,59]

In summary, hepatic and hematologic toxicities of carbamazepine are rare. Although potentially serious, they are best monitored clinically rather than by extensive or frequent laboratory testing. Patients, families, or caregivers should be aware that the appearance of unusual symptoms (eg, jaundice, abdominal pain, excessive bruising and bleeding, or sudden onset of severe sore throat with fever) should be reported to a health care professional. After initial monitoring, annual CBC and LFTs are appropriate unless signs or symptoms of hepatic or hematologic disorders are observed.

PHARMACOKINETICS AND AUTOINDUCTION OF METABOLISM

Case 60-1, Question 5: A.R.'s carbamazepine dosage was gradually increased over 6 weeks to 400 mg twice daily (bid) (20 mg/kg/day). Until the last dose increase, she had been experiencing one or two focal seizures weekly. She had experienced only one generalized tonic–clonic seizure since her initial presentation. One week after the increase to 20 mg/kg/day, her serum carbamazepine concentration was 9 µg/mL just before her first dose of the day. No seizures occurred for 4 weeks, and she tolerated the medication well. After 4 weeks, she again began experiencing one seizure weekly. What factor(s) might be responsible for the loss of seizure control?

Several factors may account for this change. It is important always to consider the possibility of poor medication adherence when clinical response changes unexpectedly. This should be investigated, and A.R. and her family should be educated regarding the importance of medication adherence.

The observed changes in A.R.'s seizure control may also be because of unique features of carbamazepine pharmacokinetics. Carbamazepine is a potent inducer of hepatic cytochrome P-450 3A4 (CYP3A4). As a result, carbamazepine not only induces the metabolism of other CYP3A4 substrates but also induces its own metabolism by autoinduction. Carbamazepine's half-life after single acute doses is ~35 hours; with chronic dosing, its half-life decreases to 15 to 25 hours. This increase in clearance necessitates increased carbamazepine doses, increased frequency of administration, or both. Autoinduction of carbamazepine metabolism appears to be related to the dose and serum concentration. Approximately 1 month may be required for the autoinduction process to reach steady state after initiation or an increase in carbamazepine dose.[60]

Assuming good adherence, A.R.'s carbamazepine dose should be increased to overcome the autoinduction. The drug's pharmacokinetics are generally linear with respect to acute dosage changes.[61] A 50% increase in dosage to 1200 mg/day should re-establish seizure control. Depending on A.R.'s clinical status, further increases in dosage may be necessary.

BIOEQUIVALENCE OF GENERIC CARBAMAZEPINE PRODUCTS

Case 60-1, Question 6: A.R.'s dosage was increased to 600 mg bid. Four weeks later, she was still experiencing one focal seizure weekly. A repeat trough serum carbamazepine concentration was 6.5 µg/mL. A.R. denied missing doses of medication, and a tablet count confirmed good adherence to the prescribed regimen. A.R. reports mild nausea after administration, but she denies vomiting. You discover that A.R.'s dispensing pharmacy recently begun substituting generic carbamazepine tablets for the brand product. What role, if any, might this carbamazepine product change have played in the failure of A.R.'s serum concentrations to increase as expected? What other factors might be considered in explaining this situation?

Several manufacturers make generic carbamazepine tablets. Bioavailability data supplied by the manufacturers are based on single-dose or short multiple-dose studies in healthy subjects. Therefore, it is impossible to completely predict the results of a change from the brand to generic carbamazepine product during maintenance therapy in an individual patient.[62] Variations in brand and generic products may cause some patients with epilepsy to experience changes in seizure control or drug toxicity when transitions between brand and generic products for several ASDs, a term known as generic-brittle.[63] However, two bioequivalence studies found no evidence of pharmacokinetic differences between brand and generic products of lamotrigine in patients with epilepsy.[64,65]

Data suggest that the generic carbamazepine products currently on the market may be substituted safely for the brand product. Nonetheless, in A.R.'s case, substitution of generic carbamazepine may be a possible cause for the loss of seizure control. Readjustment of her dose to gain seizure control or consistent use of one product (either brand or generic) might alleviate this problem. Furthermore, switching to an extended-release formulation offers an alternative for A.R. Many patients tolerate extended-release formulations of carbamazepine better because large fluctuations in plasma concentrations are avoided. Three extended-release forms of carbamazepine are available (Tegretol® XR, Carbatrol®, and Equetro®) and are dosed every 12 hours. Tegretol® XR compared with three and four times daily immediate-release carbamazepine dosing schedules may improve adherence.[66] An important counseling point for patients is that the empty osmotic-controlled-release oral delivery system (OROS) tablet shell from the Tegretol® XR does not dissolve as it passes through the gastrointestinal (GI) tract and may be visible in the stool. Tegretol® XR tablets should not be broken or crushed; Carbatrol® beads may be administered on food or via feeding tube.[67] Equetro® is not FDA (United States Food and Drug Administration) approved for epilepsy; it is indicated for the treatment of acute manic and mixed episodes associated with bipolar I disorder.

In conclusion, it may be impossible to identify a single cause for the unexpected change in A.R.'s seizure control. Common reasons for loss of seizure control include seizure triggers such as sleep deprivation, increased stress, acute illness, and/or medication nonadherence. Controversy remains surrounding the impact of switching between generic and brand ASD products but should be considered when assessing seizure control in patients with epilepsy.

Treatment Failure and Alternative Antiseizure Drugs

CASE 60-2

QUESTION 1: R.H., a 19-year-old, 141.09-pound (64-kg) female, has experienced focal seizures, with and without impaired awareness, and secondary generalized tonic–clonic seizures for the past 2 years. She could not tolerate treatment with phenytoin (severe gingival hyperplasia and mental "dullness") or valproate (hair loss, tremor, and a weight gain of 8 kg). In addition, neither phenytoin nor valproate was dramatically effective in reducing her seizures. She currently receives carbamazepine 600 mg three times daily (tid). For the past 3 months, while being treated with carbamazepine, she has had approximately five focal seizures without impaired awareness, three focal seizures with impaired awareness, and one generalized tonic–clonic seizure. This represents an approximate 30% reduction in her frequency of seizures. She tolerates her present dose of carbamazepine but has experienced significant drowsiness, incoordination, and mental confusion at higher doses.

What are possible therapeutic options for R.H.? Evaluate the newer ASDs and their possible usefulness for R.H.

R.H. is exhibiting an incomplete response to maximally tolerated doses of carbamazepine. An alteration in her current ASD regimen is indicated. She has not tolerated other ASDs because of adverse effects. Although valproate is effective for control of focal seizures, it is not considered an alternative in a female of childbearing age. R.H.'s CNS adverse effects (eg, persistent drowsiness) with other ASDs would make many clinicians reluctant to consider medications such as phenobarbital or primidone as either alternatives or adjunctive agents to her current carbamazepine regimen. Use of one

of the newer ASDs as adjunctive medication may be of value for R.H.

New ASDs marketed in the United States since 1993 for maintenance treatment of epilepsy include the following: cenobamate, eslicarbazepine, felbamate, gabapentin, lacosamide, lamotrigine, levetiracetam, oxcarbazepine, perampanel, pregabalin, tiagabine, topiramate, and zonisamide (**Table 60-5**).[68] Clinical trials for new ASDs are most often carried out in patients with focal seizures refractory to standard ASDs.[69] Most of these newer or "second-generation" ASDs were initially FDA approved as "add-on" or adjunctive treatment in patients with focal seizures with or without secondary generalization. Also, consensus is that some of these ASDs may be effective as broad-spectrum agents; for example, lamotrigine appears to be a useful treatment in absence seizures.

Table 60-5
Drugs Used for the Treatment of Seizures

ASD	Mechanism of Action	Regimen	Adverse Effects	Comments
Brivaracetam (Briviact®)	Modulates neurotransmitter release through binding to the synaptic vesicle protein SV2A	■ Initial 50 mg bid ■ May titrate based on response by increasing or decreasing 10–50 mg/day; maximum 200 mg/day ■ Children 4–16 years old: ■ If >50 kg, refer to adult dosing ■ If 20–50 kg, initial dose starts from 0.5 to 1 mg/kg/day; maximum 4 mg/kg/day ■ If 11–20 kg, initial dose 0.5 to 1.25 mg/kg/day; maximum 5 mg/kg/day	■ Sedation ■ Fatigue ■ Nystagmus ■ Irritability ■ Aggressive behavior ■ Anxiety ■ Decrease neutrophils ■ Psychosis ■ Bronchospasm	■ Dose adjustment required for patients with hepatic impairment ■ A substrate of CYP2C19, which may be impacted by genomics ■ May convert patients from levetiracetam to brivaracetam if patients cannot tolerate the psychiatric adverse effects
Cannabidiol (Epidiolex®)	Unknown	■ Initial 2.5 mg/kg bid; maximum 10 mg/kg bid ■ May ↑ by 2.5 mg/kg bid weekly	■ Somnolence ■ Sleep disorder ■ Asthenia ■ Fatigue ■ Decrease appetite ■ Diarrhea ■ Hepatotoxicity	■ May increase lamotrigine and clobazam levels ■ CYP2C19 inhibitor ■ May increase the risk for hepatotoxicity while on valproate therapy
Carbamazepine (Tegretol®, Tegretol® XR, Carbatrol®, Equetro®)	Inhibits sodium channels	■ Initial 200 mg bid (adults) or 100 mg bid (children) ■ ↑ weekly until therapeutic response or target serum concentrations ■ Usual maintenance doses 7–15 mg/kg/day in adults; 10–40 mg/kg/day in children	■ Sedation ■ Visual disturbance may limit dosage ■ Severe blood dyscrasias extremely rare ■ Mild leukopenia more common ■ Asian patients positive for HLA-B*1502 are at 10-fold higher risk for Stevens–Johnson syndrome/toxic epidermal necrolysis ■ Hepatotoxicity rare ■ May cause hyponatremia ■ Long-term use may cause osteomalacia	■ Usually, little sedation and minimal interference with cognitive function or behavior ■ Preferred by most for focal or secondary generalized seizures ■ Extended-release products may allow less frequent dosing with fewer peak serum concentration-related adverse effects. These products may also facilitate adherence
Cenobamate (Xcopri®)	Inhibits sodium channels and may increase GABA activity	■ Initial 12.5 mg/day for weeks 1–2 ■ Increase biweekly as tolerated by doubling the dose until 100 mg in week 7 then increase by 50 mg/day biweekly ■ Maximum 400 mg/day	■ QT shortening ■ Hypersomnia ■ Lethargy ■ Malaise ■ Hyperkalemia ■ Visual disturbance ■ Diplopia	■ Slow titration required to avoid hypersensitivity reactions (eg, DRESS) ■ Not approved for pediatrics ■ Avoid use in end-stage renal or liver disease ■ Consider gradual withdrawal over at least 2 weeks, and if on chronic therapy may decrease dosing over 2–6 months ■ Contraindicated in patients with familial short QT syndrome

Clobazam (Onfi®; Sympazan®)	Increases GABA activity	■ Initial 5 mg bid, then double the dose every week to the desirable effect ■ No established maximum dose ■ In older adults, start with 5 mg once daily and double the dose every week	■ Sedation ■ Lethargy ■ Drooling ■ Aggressive behavior ■ Irritability ■ Ataxia ■ Fever ■ Possible upper respiratory tract infection	■ Boxed warning for concomitant use of benzodiazepines and opioids ■ Has off-label use as an adjunctive in refractory seizures ■ Needs dose adjustment upon initiation for patients with liver disease ■ Major substrate of CYP2C19
Eslicarbazepine (Aptiom®)	Inhibits sodium channels	■ Initial 400 mg once daily ■ ↑ by 400 mg/day after one week ■ Maximum recommended dose is 1200 mg/day ■ Once-daily dosing recommended	■ Dizziness ■ Somnolence ■ Nausea ■ Headache	■ Enzyme-inducing ASDs reduce eslicarbazepine exposure; thus, higher doses may be needed ■ May reduce effectiveness of hormonal contraceptives
Ethosuximide (Zarontin®)	Inhibits calcium channel	■ Initial 20 mg/kg/day or 250 mg daily or bid ■ ↑ by 10 mg/kg/day or 250 mg/day every 2 weeks to therapeutic effect or target serum concentration	■ GI upset and sedation common with a large single dose, especially upon initiation ■ Divided doses may be necessary for tolerability ■ Leukopenia (mild, transient) in up to 7% ■ Serious hematologic toxicity extremely rare	■ Parents/patient should be educated on GI effects and sedation, but tolerance usually develops ■ Administration with food can alleviate GI upset ■ Effective for absence seizures ■ Evidence does not support precipitation of tonic–clonic seizures
Felbamate (Felbatol®)	Increases GABA activity and antagonizes NMDA receptor	■ Initial 1.2 g/day in three to four divided doses ■ For monotherapy increase by 600 mg/day every 2 weeks ■ For adjunctive therapy, increase by 1.2 mg/day every week	■ Anorexia ■ Insomnia ■ Headache ■ Dizziness ■ Somnolence ■ Increases the risk for infections ■ Serious liver damage	■ Boxed warning for aplastic anemia and acute liver failure ■ Increases phenytoin, valproic acid, phenobarbital, and carbamazepine levels; therefore, reduce the dose for these agents by 20% upon initiation of felbamate ■ Might be considered for refractory seizures
■ Fosphenytoin (Cerebyx®) ■ Phenytoin (Dilantin®, Phenytek®)	Inhibits sodium channels	■ Initiate at maintenance dose of 4–5 mg/kg/day (300–400 mg/day) ■ Titrate on basis of clinical response and target serum concentration ■ Waiting for 3–4 weeks between doses is recommended before increasing the dose because of potentially slow accumulation	■ Nystagmus ■ Ataxia ■ Sedation may limit dosage ■ Gum hyperplasia ■ Hirsutism ■ Long-term use may cause osteomalacia ■ Peripheral neuropathy, hypersensitivity with liver damage rare ■ Possible increased risk of Stevens–Johnson syndrome/toxic epidermal necrolysis in Asian patients positive for HLA-B*1502	■ Clearance and half-life change with dose ■ Small ↑ in dose (30-mg capsule) recommended as plasma concentrations exceed 7–10 μg/mL ■ Cautious use of suspension; dose measurement and potential mixing difficulties along with potential interactions with tube feeding formula ■ IM administration not recommended

				■ Potential precipitation in IV solutions ■ Fosphenytoin recommended for IM and IV use because of faster administration rate, admixture compatibility, and lower rate of injection site complications
Gabapentin (Neurontin®)	Inhibits calcium channels	■ Initial 300 mg/day with titration to 900–1800 mg/day for 1–2 weeks ■ Doses of 2400 mg/day and higher have been well tolerated ■ Owing to short half-life, tid or qid dosing recommended	■ Common with initiation of therapy ■ Sedation ■ Dizziness ■ Ataxia ■ Commonly associated with weight gain	■ Excreted unchanged by kidneys ■ No significant drug–drug interactions ■ Absorption dose dependent; fraction absorbed ↓ as size of individual dose ↑
Lacosamide (Vimpat®)	Inhibits sodium channels	■ Initiate at 50 mg bid ■ Increase weekly by 100 mg/day ■ Target doses of 200–400 mg/day ■ Maximum recommended dose is 400 mg/day	■ Dizziness ■ Ataxia ■ Diplopia ■ Headache ■ Nausea ■ May slow cardiac conduction via inhibition of the cardiac sodium channels; caution is advised in patients with second-degree AV block ■ Syncope has been reported	■ Currently only indicated for treatment of focal seizures in adults ■ IV form available; currently only approved for short-term replacement of oral therapy ■ Little evidence of significant risk of drug–drug interactions ■ Some hepatic metabolism by CYP2C19; significant renal elimination
Lamotrigine (Lamictal®)	Inhibits sodium channels	■ *When added to enzyme inducers alone:* ■ Initiate at 50 mg daily HS or 50 mg bid ■ Daily dose can be ↑ by 50–100 mg every 7–14 days ■ Usual maintenance doses of 400–500 mg/day ■ Bid dosing may be necessary with enzyme inducer co-therapy ■ *When added to valproate alone:* ■ Initiate at 25 mg qod HS ■ Daily dose can be ↑ by 25 mg every 14 days ■ Usual maintenance doses of 100–200 mg/day ■ *For patients not taking valproate or an enzyme inducer:* ■ Initiate at 25 mg once-daily HS ■ Daily dose can be ↑ by 25 mg every 14 days ■ Usual daily doses of 225–375 mg/day	■ Common with initiation of therapy; may limit speed of titration ■ Dizziness ■ Diplopia ■ Sedation ■ Ataxia ■ Blurred vision ■ Incidence of serious rash ranges from 0.8 to 8 per 1000	■ Significant ↑ in clearance of lamotrigine when coadministered with enzyme inducers ■ Significant ↓ in clearance when coadministered with valproate ■ Slow, gradual titration of dose may reduce risk of skin rash ■ Estrogen increases clearance
Levetiracetam (Keppra®, Keppra®-XR, Spritam®)	Modulates neurotransmitter release through binding to the synaptic vesicle protein SV2A	■ Initial 250–500 mg bid ■ ↑ by 500–1000 mg/day every 2 weeks ■ Usual maximal dose is 3000 mg/day ■ Doses up to 4000 mg/day have been used ■ Bid dosing recommended	■ Somnolence ■ Dizziness ■ Asthenia ■ Behavioral symptoms (agitation, emotional lability, hostility, depression, and depersonalization) reported	■ No hepatic metabolism ■ 66% excreted unchanged in urine ■ Less than 10% protein bound ■ No significant drug interactions reported
Oxcarbazepine (Trileptal, Oxtellar®)	Inhibits sodium channels	■ *Monotherapy:* ■ Initial 300 mg bid ■ ↑ weekly up to 1200 mg/day ■ Can increase to 2400 mg/day ■ *Adjunctive therapy:* ■ Initial 300 mg bid ■ ↑ weekly up to 1200 mg/day	■ Dizziness ■ Somnolence ■ Diplopia ■ Nausea ■ Ataxia ■ May cause hyponatremia; most cases asymptomatic, more common in older adults ■ A 25% cross-sensitivity for skin rash reported between oxcarbazepine and carbamazepine	■ Parent is a prodrug; the MHD is the active component ■ Readily converted to MHD via omnipresent cytosolic enzymes ■ Lacks autoinduction properties ■ In doses >1200 mg/day, may affect oral contraceptives
Perampanel (Fycompa®)	Inhibits (AMPA) glutamate receptor	■ Initial 2 mg once-daily HS (not on enzyme-inducing ASDs) ■ OR ■ 4 mg once-daily HS (on enzyme-inducing ASDs) ■ ↑ by 2 mg/day every week ■ 4–12 mg/day recommended as target dosage range ■ Once-daily dosing HS recommended	■ Dizziness ■ Gait disturbance ■ Somnolence ■ Fatigue ■ Risk of falls in older adult patients ■ Aggression ■ Hostility ■ Irritability ■ Anger ■ Homicidal ideation ■ Adverse effects may be worsened by alcohol	■ Avoidance of alcohol is recommended ■ Enzyme-inducing ASDs reduce perampanel exposure by 50%–67%; higher doses may be needed ■ Perampanel 12 mg/day may reduce effectiveness of hormonal contraceptives containing levonorgestrel ■ Boxed warning for serious or life-threatening psychiatric and behavioral adverse effects
Phenobarbital	Prolongs opening of GABA receptors	■ Initial 1 mg/kg/day; titrate to therapeutic response ■ For full dose response, wait for 2–3 weeks between doses	■ Sedation (chronic) ■ Behavior disturbances common, especially in children ■ Possibly impairs learning and intellectual performance ■ Long-term use may cause osteomalacia	■ Considered outmoded for ASD therapy in most patients ■ Adverse effects outweigh benefits ■ IV use for refractory status epilepticus
Pregabalin (Lyrica®)	Inhibits calcium channels	■ Initial 50 mg bid ■ Titrate to therapeutic response with maximal daily dose at 600 mg/day in divided doses (bid or tid)	■ Dizziness ■ Blurred vision ■ Weight gain	■ No significant interactions with other ASDs ■ Can be useful for patients with concomitant pain disorders

Primidone (Mysoline®)	Prolongs opening of GABA receptors	■ Initial 100–125 mg/day ■ Usual dose 750–1500 mg/day ■ In divided doses 3–4/day ■ Maximum 2000 mg	■ Nystagmus ■ Diplopia ■ Fatigue ■ Drowsiness ■ Emotional disturbances ■ Blood dyscrasias ■ Liver dysfunction ■ Rarely causing SJS	■ Valproate may increase its level, whereas phenytoin may decrease it ■ May decrease concentration of AntiXa anticoagulation drugs ■ Contraindicated in patients with porphyria
Rufinamide (Banzel®)	Inhibits sodium channels	■ Initial 200–400 mg/bid ■ Increase by 200–400 mg/bid every other day ■ Maximum 3200 mg bid ■ Initial dose in children is 10 mg/kg bid, and increase by the same amount every other day	■ QT shortening ■ Drowsiness ■ Headache ■ Vomiting ■ Nausea	■ No renal or hepatic dose adjustment ■ On discontinuation reduce the dose by 25% every 2 days ■ Should be taken with food ■ Contraindicated in patients with familial short QT syndrome
Stiripentol (Diacomit®)	May enhance GABA activity	■ Initial 10–15 mg/kg/day ■ May divide the amount in two to three doses ■ Titrate to a target dose of 50 mg/kg/day over 2–4 weeks ■ Maximum 3 g/day	■ Decreased appetite ■ Drowsiness ■ Agitation ■ Ataxia ■ Hypotonia ■ Tremor ■ Decreased platelet and neutrophil count	■ Used as adjunctive therapy for Dravet syndrome ■ Multiple drug interactions as it is a major substrate of CYP3A4 and moderately inhibits CYP2C19
Tiagabine (Gabitril®)	Inhibits GABA reuptake	■ Initial 4 mg/day ■ ↑ by 4 mg/day at 7 days; then ↑ daily dose by 4–8 mg every week ■ Maximal recommended dose of 32 mg/day in adolescents or 56 mg/day in adults ■ Bid to qid dosing recommended	■ Drowsiness ■ Nervousness ■ Difficulty with concentration or attention ■ Tremor ■ Nonspecific dizziness described by some patients	■ Increased clearance when given with enzyme inducers ■ Tid or qid doses probably needed ■ Potential for protein-binding displacement interactions with other highly protein-bound drugs (eg, valproate) ■ Significance of protein-binding displacement not known ■ Substrate for CYP3A4
Topiramate (Topamax®, Trokendi®, Qudexy®)	Inhibits sodium channels and activates GABA receptors, inhibits glutamate receptors	■ Initial 50 mg HS ■ ↑ daily dose by 50 mg every 7 days ■ 200–400 mg/day recommended as target dosage range ■ Larger daily doses associated with increased CNS adverse effects ■ Bid dosing recommended	■ May be dose related: ■ Sedation ■ Dizziness ■ Difficulty concentrating ■ Confusion ■ Possible weight loss ■ Weak CA inhibitor; may cause or predispose to kidney stones; CA inhibition also possibly related to paresthesias in up to 15% ■ Risk of hypohidrosis and hyperthermia especially in children ■ Rarely associated with angle-closure glaucoma	■ Approximately 70% renal elimination ■ Phenytoin and carbamazepine may reduce topiramate plasma concentrations and potentially increase dosage requirements ■ Topiramate may cause small ↑ in phenytoin plasma concentration ■ Advise patients to drink plenty of fluids ■ May affect oral contraceptives above 200 mg/day
Valproate (Depakene®, Depakote®, Depakote®-ER)	Increase activity of GABA, inhibits sodium channel	■ Initial 5–10 mg/kg/day (sprinkle caps or syrup) ■ ↑ by 5–10 mg/kg/day weekly to therapeutic effect or target serum concentration ■ Daily dosing recommended for ER product ■ Doses should be 8%–20% higher than non-ER products	■ GI upset ■ Hair loss ■ Appetite stimulation ■ Weight gain ■ Dose-related tremor and thrombocytopenia may occur ■ Serious hepatotoxicity extremely rare with monotherapy	■ Enteric-coated products or ER tablets may ↓ GI upset ■ Time to peak serum concentrations delayed for 3–8 hours with enteric coating; longer delay if given with food ■ Effective against primarily generalized tonic–clonic and absence seizures ■ Young children are generally at a higher risk for serious hepatotoxicity, but it can occur at any age ■ Monitor LFTs and platelet count
Vigabatrin (Sabril®, Vigadrone®)	Irreversibly inhibits GABA transaminase that increases GABA concentration	■ Initial 500 mg bid ■ Titrate in increments of 500 mg weekly ■ Usual dose 1500 mg bid ■ No established maximum dose in adults	■ Skin rash ■ Weight gain ■ Viral infection ■ Vomiting ■ Constipation ■ Dizziness ■ Drowsiness ■ Fatigue ■ Tremor ■ Blurred vision ■ Nystagmus ■ Vision loss	■ Boxed warning for permanent vision loss ■ Ophthalmic examination every 3–6 months is recommended ■ On discontinuation reduce by 1 g/day every week ■ Require dose adjustment in patients with renal impairment
Zonisamide (Zonegran®)	Inhibits sodium and calcium channels	■ Initial 100 mg daily ■ ↑ by 100 mg/day every 2 weeks ■ Usual maintenance doses of 200–400 mg/day ■ Maximum 600 mg/day	■ Somnolence ■ Nausea ■ Ataxia ■ Dizziness ■ Headache ■ Anorexia ■ Weight loss ■ Nephrolithiasis ■ Serious skin eruptions, oligohidrosis, and hyperthermia have also occurred	■ Broad spectrum, long half-life ■ 35% of dose is excreted unchanged in the urine ■ A substrate of CYP3A4; enzyme induction may increase clearance ■ Advise patients to drink plenty of fluids

ASD, antiseizure drugs; AV, atrioventricular; bid, twice daily; CA, carbonic anhydrase; CNS, central nervous system; CYP, cytochrome P-450; DRESS, drug reaction with eosinophilia and systemic symptoms; ER= extended release; GABA,

gamma-aminobutyric acid; GI, gastrointestinal; HS, at bedtime; IM, intramuscular; IV, intravenous; LFT, liver function test; MHD, monohydroxy derivative; NMDA, *N*-methyl-D-aspartate; qid, four times daily; qod, every other day; SJS, Stevens-Johnson syndrome; tid, three times daily.

ADVERSE EFFECTS

Common adverse effects for ASDs are described in Table 60-5. Most of them are less sedating than older medications such as phenobarbital or phenytoin. The most common adverse effects seen in the clinical trials with eslicarbazepine were ataxia, blurred and double vision, dizziness, fatigue, headache, nausea, somnolence, tremor, vertigo, and vomiting.[70]

Cenobamate is one of the newest ASDs, and therefore limited data exist for adverse effects. In clinical trials, the most common adverse effects were somnolence, dizziness, fatigue, diplopia, and headache. Serious adverse events included drug reaction with eosinophilia and systemic symptoms (DRESS) and QT shortening.[71]

Gabapentin and tiagabine have not been associated with serious adverse effects; gabapentin can cause weight gain,[72] and tiagabine can cause nonspecific dizziness relatively frequently.[73]

Common adverse effects associated with lacosamide include dizziness, headache, diplopia, nausea, and dose-dependent per rectum (PR)-prolongation. Gradual escalation to the desired dose reduces the adverse event risk.

The most serious adverse effect associated with lamotrigine is skin rash. Rashes occur in ~10% of treated patients, usually in the first 8 weeks.[74] Rashes leading to hospitalization occurred in 1 of 300 adults and 1 of 100 children. Widespread, maculopapular rashes usually appear and may progress to erythema multiforme or toxic epidermal necrolysis. Lamotrigine-related rashes may resolve rapidly when lamotrigine is discontinued. Coadministration of valproate with lamotrigine may increase the likelihood of dermatologic reactions; it is partly for this reason that more conservative dosage titration and lower maintenance doses of lamotrigine are recommended for patients receiving concomitant valproate. Higher starting doses and

more rapid dose escalation than those recommended by the manufacturer also increase the risk of skin rash.

Levetiracetam is generally well tolerated, with the most common adverse events in clinical trials being asthenia, vertigo, flu syndrome, headache, rhinitis, and somnolence. The most serious adverse effects are behavioral and are more common in patients with a history of behavioral problems.[75] Levetiracetam should be used with caution in patients with a history of suicidal ideations.

Oxcarbazepine, a keto derivative of carbamazepine, is essentially a prodrug for the monohydroxy active metabolite.[76] Oxcarbazepine probably causes less frequent, less severe adverse effects compared with carbamazepine, with the exception of hyponatremia. Hyponatremia is more common with oxcarbazepine than with carbamazepine. Baseline and periodic serum sodium monitoring is indicated during oxcarbazepine therapy. The most commonly reported adverse effects of oxcarbazepine in clinical trials include ataxia, dizziness, fatigue, nausea, somnolence, and diplopia.

Adverse effects of pregabalin are dose dependent and usually occur within the first 2 weeks of treatment.[77] Somnolence, dizziness, and ataxia are the most common. Pregabalin also appears to be associated with a dose-related weight gain.

Topiramate can cause cognitive disturbances, lethargy, and impaired mental concentration when given in large daily doses (especially in combination with other ASDs) or when the dosage is titrated too aggressively.[78] Topiramate has caused nephrolithiasis in ~1.5% of treated patients. This adverse effect is believed to be related to the inhibition of carbonic anhydrase by topiramate, with resulting increased urinary pH and decreased citrate excretion. Topiramate can also cause acute, secondary angle-closure glaucoma, which presents within the first month of therapy. Topiramate is associated with weight loss.

Zonisamide is a sulfonamide derivative and thus is contraindicated in patients allergic to sulfonamides.[79] The most commonly reported adverse events include ataxia, somnolence, agitation, and anorexia. Kidney stones have developed in 3% to 4% of patients, some of whom had a family history of nephrolithiasis.

PHARMACOKINETICS

The newer ASDs have somewhat different pharmacokinetic profiles from those of older agents. They also differ in their tendency to interact with other ASDs. Gabapentin is excreted entirely by the kidneys as unchanged drug and is not significantly bound to plasma protein. Gabapentin has a relatively short half-life and should be administered three times daily.[80]

Cenobamate is extensively metabolized by glucuronidation via UGT2B7 and by oxidation via CYP2E1, CYP2A6, and CYP2B6. With a long half-life of 50–60 hours, cenobamate can be administered once daily.[71]

Lacosamide is excreted mostly by the kidneys. Dosage reductions are warranted for patients with renal impairment (creatinine clearance <30 mL/minute). It is <15% bound to plasma protein, has a 12- to 13-hour half-life, and is administered twice daily.[81]

Lamotrigine is primarily eliminated by hepatic glucuronidation and excretion of metabolites in the urine. Other ASDs, such as carbamazepine and phenytoin, induce the hepatic metabolism of lamotrigine. When lamotrigine is coadministered with enzyme-inducing drugs, its half-life decreases from ~24 to 15 hours. Valproate inhibits lamotrigine metabolism, causing increases in half-life and serum concentrations.[82,83] Patients treated with both lamotrigine and carbamazepine may experience more nausea, drowsiness, and ataxia. It appears likely that this interaction represents a pharmacodynamic interaction between lamotrigine and carbamazepine.[84]

Levetiracetam has a short half-life and is eliminated primarily by renal mechanisms. Dosage reductions are warranted for patients with renal impairment (creatinine clearance <80 mL/minute). The drug has a low potential for interactions with other drugs.[85]

Both eslicarbazepine acetate and oxcarbazepine are prodrugs. They cause less hepatic enzyme induction than carbamazepine and may therefore be less likely to interact with other medications. Both, however, increase the metabolism of oral contraceptive hormones.[86,87] Because eslicarbazepine and oxcarbazepine have

similar mechanisms of action to that of carbamazepine, it is unlikely that either would offer significant benefits to R.H. because she has not responded to maximal tolerated doses of carbamazepine.[70,76]

Pregabalin is excreted entirely by the kidneys as unchanged drug and is not significantly bound to serum proteins. Unlike gabapentin, which requires more frequent dosing, pregabalin can be administered two or three times daily.[77]

Tiagabine has a relatively short half-life (4–7 hours). It should be administered at least twice daily.[73] Concurrently administered enzyme-inducing ASDs may reduce the half-life of tiagabine to 2 to 3 hours and necessitate use of larger daily doses and, possibly, shorter dosing intervals. Tiagabine is highly protein bound (96%), and it is displaced from protein-binding sites by valproate, salicylate, and naproxen. The clinical significance of these protein-binding interactions is unknown.

Topiramate has a half-life of ~20 hours, which allows twice-daily administration. It is only partially excreted by hepatic metabolism; ~70% of the drug is excreted unchanged by the kidneys. Topiramate is minimally protein bound (~10%–15%). When topiramate is coadministered with enzyme-inducing agents, topiramate clearance is increased. This interaction may necessitate titration to somewhat higher doses when topiramate is used with enzyme-inducing drugs.

Zonisamide has a long half-life and low protein binding. It is eliminated by both hepatic metabolism and renal excretion. The average half-life of zonisamide is 63 hours, but there is wide interpatient variation. Serum levels of zonisamide are reduced by enzyme-inducing ASDs, but clinical consequences of pharmacokinetic interactions with zonisamide are rare.[79]

On the basis of efficacy and adverse effect characteristics, cenobamate, gabapentin, lacosamide, lamotrigine, levetiracetam, pregabalin, tiagabine, topiramate, or zonisamide could be considered for use as adjunctive therapy for R.H. In young, active patients such as R.H., sedation might prove to be a problem; however, it is not clear that any of these drugs predictably causes more initial or long-term sedation. The short half-lives of gabapentin and tiagabine and the associated need for R.H. to take several

doses during the day might decrease her adherence. Therefore, cenobamate, lacosamide, lamotrigine, levetiracetam, pregabalin, topiramate, or zonisamide would be reasonable choices on the basis of convenience. Because the patient is not tolerating carbamazepine, it does not make sense to switch to either eslicarbazepine or oxcarbazepine.

The reason felbamate and perampanel were not discussed in the Adverse Effects and Pharmacokinetics sections above is that these authors do not believe they are good options for R.H. at this point. Perampanel has an FDA box warning (behavioral reactions). Felbamate's usefulness is seriously limited by its association with aplastic anemia and hepatic failure.

POTENTIAL THERAPIES

Other ASDs that may become available in the near future include fenfluramine, padsevonil, ganaxolone, and huperzine A.[88–90] These drugs may become useful as alternatives or adjuncts to established and newer medications in the future.

With advancing technology and knowledge about genes and brain networks, future treatment strategies should move from controlling symptoms of epilepsy with ASDs to prevention and cure. For ASD-resistant epilepsy, much research is examining the role of multidrug transporters (eg, *P*-glycoprotein) at the blood–brain barrier. These proteins may act as a defense mechanism by limiting the accumulation of ASD in the brain.[91] Although it has not yet had much of an impact on the clinical care of patients with epilepsy, pharmacogenetics of ASD therapy is continually advancing.[92]

Lamotrigine Therapy

INITIATION AND DOSAGE TITRATION

Case 60-2, Question 2: R.H. is to be started on lamotrigine as adjunctive therapy to her carbamazepine. Outline a treatment plan for initiating and monitoring therapy for R.H. What should R.H. and her family be told about this medication and how to use it?

Lamotrigine therapy should be initiated in R.H. with a slow upward dosage titration to minimize early sedative effects and reduce the likelihood of skin rash. An initial dosage of 50 mg/day given at bedtime is recommended; the daily dose can be increased by 50 mg every 1 to 2 weeks. Because R.H. is currently receiving carbamazepine, induction of liver enzymes is likely to increase her dosage requirements for lamotrigine and allow a less conservative dosage titration. A twice-daily schedule is recommended for maintenance therapy. Usual maintenance dosages of lamotrigine are ~300 to 500 mg/day. A patient's ability to tolerate this medication ultimately determines dosage limitations. Onset of adverse effects (eg, nausea, diplopia, ataxia, and dizziness) may prevent further dosage increases.

R.H. should be told that she may feel drowsy and possibly experience headache and upset stomach, but that these adverse effects usually disappear with ongoing therapy. She should contact her physician or other health care professional if severe adverse effects occur that make it difficult to take the medication; this is especially important if she exhibits a rash.

ADVERSE EFFECTS AND POSSIBLE INTERACTION WITH CARBAMAZEPINE

CASE 60-2, QUESTION 3: Two days after her dosage of lamotrigine was increased to 300 mg/day (12 weeks after beginning therapy), R.H. noticed that her vision was blurring; she also reported feeling dizzy and having difficulty maintaining her balance. Previously, she had experienced only mild, occasional nausea. She had continued to experience seizures at approximately the same frequency she had before the initiation of lamotrigine. Her physician had encouraged her to continue taking the medication and explained that it would take time to increase the dose to possibly effective levels. Her current carbamazepine serum concentration is essentially unchanged when compared with when she was taking it in monotherapy. Do these new adverse effects represent treatment failure with lamotrigine? If not, how might these new adverse effects be managed?

R.H.'s adverse effects may limit further dosage increases. Her current adverse effects might represent carbamazepine intoxication, lamotrigine adverse effects, or an interaction between these two medications. Because R.H. tolerated the same carbamazepine dose previously, carbamazepine "intoxication" seems a less likely cause. Assessing the role of lamotrigine as the only cause is difficult. Obtaining a lamotrigine serum concentration to aid in assessing her adverse effects is not likely to be helpful. A usual "therapeutic range" for lamotrigine serum concentrations has not been established. Clinical studies have failed to demonstrate a significant correlation between lamotrigine serum concentrations and either therapeutic or adverse responses.[93,94] Her symptoms may also be related to an apparent pharmacodynamic interaction between lamotrigine and carbamazepine.[84] The effects experienced by some patients taking both drugs may be relieved by reducing the carbamazepine dosage.

Levetiracetam Therapy

INITIATION AND DOSAGE TITRATION

Case 60-2, Question 4: R.H.'s carbamazepine dosage was reduced from 1800 to 1400 mg/day. After 5 days, her adverse effects persisted, and her seizure frequency appeared to be increasing. The clinician decides to abandon lamotrigine therapy and institute treatment with levetiracetam. Recommend a plan for initiating R.H.'s levetiracetam treatment. How should R.H. levetiracetam therapy be initiated?

R.H. previously tolerated and had a better therapeutic response to a higher carbamazepine dose. Therefore, the dosage of carbamazepine should be returned to 1800 mg/day before levetiracetam therapy is initiated. Little specific information is available to help determine how lamotrigine can be safely discontinued. As a general rule, rapid dose reduction or abrupt discontinuation of ASDs is not recommended in other than emergency situations. Therefore, immediate reduction of R.H.'s lamotrigine dosage to 200 mg/day would seem reasonable. This

dosage could then be reduced by 50 to 100 mg every week until lamotrigine is discontinued.

Levetiracetam treatment should be instituted immediately for R.H. because of her continuing seizures. Levetiracetam does not interact with other ASDs. Therefore, discontinuing lamotrigine during initiation of levetiracetam should not create difficulties in assessing R.H.'s response. Levetiracetam should be initiated at a dosage of 250 to 500 mg two times daily.[85] Although the manufacturer recommends initiating treatment at 500 mg twice daily, patients may better tolerate lower initial doses and more gradual titration. R.H.'s daily levetiracetam dose can be increased by 500 to 1000 mg every 2 or 3 weeks, according to her tolerance of adverse effects and her change in seizure frequency. Although the drug reaches steady state quickly, allowing at least 2 weeks for observation before dosage increases may improve patient tolerability and allow for a more thorough evaluation of therapeutic response. At present, the relationship between serum concentrations of levetiracetam and therapeutic response or symptoms of intoxication is not well defined. Therefore, R.H.'s dose should be titrated to the maximal tolerated amount required to control her seizures. In controlled trials, no clear benefits were apparent at doses >3000 mg/day.

PATIENT EDUCATION

R.H. should be informed that with levetiracetam she may experience adverse effects similar to those she had with lamotrigine. R.H.'s mood should be assessed at each visit. Much reassurance and encouragement may need to be given along with this information to help ensure that R.H. adheres to her treatment regimen. Many patients become discouraged when multiple trials of medication are necessary and adverse effects are prominent.

Given that R.H.'s seizures are still not well controlled, driving restrictions that were likely put into place earlier should be continued. R.H. should be counseled not to drive until she is seizure-free, and her driving privileges have been reinstated according to applicable

state law. This restriction can be very hard for some patients to accept because it can significantly decrease their independence.

Phenytoin Therapy

INITIATION AND DOSAGE

CASE 60-3

QUESTION 1: J.N., an 18-year-old, 194.01-pound (88-kg) male college student, was diagnosed with epilepsy. He experiences generalized tonic–clonic seizures that last 2 minutes approximately three times monthly. J.N. describes a "churning" feeling in his abdomen before his seizures; this is followed by involuntary right-sided jerking of his upper extremities. An EEG showed diffuse slowing with focal epileptiform discharges in the left temporal area; it was interpreted as abnormal. No correctable cause for his seizure disorder was identified despite a thorough workup. He has no other medical conditions and takes no routine medications. He was treated initially with carbamazepine up to 600 mg/day. He could not tolerate the medication because of nausea and diplopia despite relatively low doses. J.N.'s physician has elected to implement a therapeutic trial of phenytoin. Recommend an initial dosage.

What information should be provided to J.N. about his new medication?

Selecting a nontoxic, therapeutic dose of any ASD is difficult without having information about the drug's disposition in the individual patient (ie, prior dosages and clinical response). Although "average" dosages and resulting serum concentrations for phenytoin often are quoted, interpatient variability is significant. An initial phenytoin dosage of 400 mg/day (~4.5 mg/kg/day) would be appropriate for J.N. In most patients, phenytoin therapy is initiated at or near the anticipated maintenance dose (eg, 300 or 400 mg daily in J.N.). If tolerability problems arise, J.N.'s phenytoin dose could be reduced to 200 mg daily (or 100 mg every 12 hours) and increased by 100 mg/day at weekly intervals until 400 mg/day is reached. Recently, there has been significant interest in using patient-specific genetic information to more accurately dose certain drugs, including phenytoin, with the goals of achieving a therapeutic effect quickly and avoiding dose-related toxicity. Although certain CYP2C9

homozygous allele variants have been shown to confer "slow-metabolizer" status on patients treated with phenytoin,[95] CYP2C9 genotyping of patients is not presently a part of routine clinical practice.

PATIENT EDUCATION

J.N. should be informed that he may experience initial mild sedation from phenytoin. He should be cautioned that symptoms such as blurred or double vision, dysarthria, dizziness, or staggering may indicate that his dosage is too high; he should be instructed to notify his physician, pharmacist, or other health care professional of these symptoms. It is also a good idea to inform patients, at the beginning of therapy, that adjustments of medication dosage may be necessary before the regimen is stabilized. Although J.N. is at relatively low risk for osteomalacia given his age and sex, he should be informed that long-term use of phenytoin (as well as other ASDs; see Table 60-5) is associated with an increased risk of bone mineral loss and that this adverse effect warrants monitoring periodically.

ACCUMULATION PHARMACOKINETICS

CASE 60-3, QUESTION 2: What are the characteristics of phenytoin accumulation pharmacokinetics?

Phenytoin exhibits dose-dependent (Michaelis–Menten or capacity- limited) pharmacokinetics; therefore, the usual pharmacokinetic concepts of "clearance" and "half-life" are meaningless. The apparent half-life of phenytoin changes with the dose and serum concentration. Thus, the time required to reach a new steady state after dose alteration is difficult to predict because it depends on the dose itself and the patient's pharmacokinetic parameters, V_{max} and K_m.[33] V_{max} is a kinetic constant representing the maximal rate of phenytoin elimination from the body. K_m is the Michaelis constant, the serum concentration at which the rate of elimination is 50% of V_{max}. Values for these parameters vary widely

among patients; as a result, patterns of phenytoin accumulation and the time required to achieve steady state also vary.

Many clinicians assume that phenytoin's apparent half-life is ~24 hours, and they wait 5 to 7 days before assessing the patient's clinical response and measuring serum phenytoin concentrations. Both clinical studies[96] and model simulations[97] using observed values for K_m and V_{max} have been used to estimate time required for serum concentrations of phenytoin to reach steady state. Up to 30 days may be needed for this to occur either with doses sufficient to produce steady-state serum concentrations of 10 to 15 µg/mL or with doses of 4 mg/kg/day.[33,98] Occasionally, such a dose may exceed a patient's V_{max}; the result is extremely high serum phenytoin concentrations, with probable intoxication. It is important not to assume that steady state has been reached unless widely spaced, serial serum concentrations indicate that accumulation has ceased. Alterations in phenytoin dosage before steady state has been reached can result in significant fluctuations in serum concentrations and the patient's clinical status. Such situations occur frequently and result in unnecessary confusion and expense. As always, serum concentrations in J.N. must be interpreted in the context of his clinical response.

PHENYTOIN INTOXICATION

Case 60-3, Question 3: J.N. was started on phenytoin and is now taking 200 mg every 12 hours. One week after achieving this dose, mild lateral gaze nystagmus was noted, but J.N. had no subjective problems and was seizure-free. After 3 weeks, J.N. reported double vision and feeling "drunk" and "unsteady." Significant nystagmus was present. How should J.N.'s phenytoin dosage be altered?

J.N.'s signs and symptoms indicate phenytoin intoxication. Dosage reduction is indicated. Reducing J.N.'s dosage to 360 mg/day (accomplished using both 100- and 30-mg phenytoin capsules) would be reasonable. A larger reduction may result in a loss of seizure control. Many clinicians also would have J.N. omit 1 day's

dose of phenytoin before beginning the new maintenance dosage. This would accelerate the decline in phenytoin serum levels. After this dosage change, clinical response should be monitored closely. The new maintenance dose may still be excessive, if J.N.'s V_{max} for phenytoin is low. If this were the case, continued accumulation of drug would occur despite the dosage reduction.[33]

INTRAMUSCULAR PHENYTOIN AND FOSPHENYTOIN (PHENYTOIN PRODRUG)

CASE 60-4

QUESTION 1: S.D. is a 24-year-old male institutionalized patient with a history of focal seizures with impaired awareness and secondary generalized tonic–clonic seizures. Within the past year, his phenytoin formulation was switched from phenytoin sodium capsules to phenytoin suspension because S.D. was suspected of "cheeking" his medicines and not swallowing the capsules. He has had no seizures in the past 3 months on 275 mg/day of phenytoin suspension. S.D. has now been transferred to the acute medical unit after a 2-day history of anorexia, nausea, occasional vomiting, and abdominal pain accompanied by diarrhea. His chart now states, "nothing by mouth." IM phenytoin, 275 mg (phenytoin sodium equivalents [PEs]) per day, has been ordered.

Should IM phenytoin be used for S.D.? What is the ideal dosage regimen?

S.D. is a candidate for parenteral administration of his ASD. If placement of an IV line is not planned, then IM administration is an acceptable approach to treatment; however, the type of phenytoin product administered will need to be changed. Phenytoin, itself, should not be administered by IM injection. Injectable phenytoin is highly alkaline (pH 12) and extremely irritating to tissue. After IM injection, the drug may precipitate at the injection site because of the change in pH. As a result, phenytoin crystals form a repository or depot from which the drug is slowly absorbed.[99–101] Often injection site discomfort is noted, although severe muscle damage does not seem to occur.[101]

Fosphenytoin, a phosphate ester prodrug of phenytoin, is highly water-soluble. Its solubility allows this preparation to be administered

parenterally without the need for solubilization using propylene glycol or the adjustment of pH to nonphysiologic levels. Therefore, fosphenytoin may be administered either IM or IV with less risk of tissue damage and venous irritation than with parenteral administration of phenytoin.[102–104] (See also subsequent discussion of IV administration of phenytoin and fosphenytoin.) After administration, fosphenytoin is rapidly absorbed and converted to phenytoin by phosphatase enzymes. Ultimately, the bioavailability of phenytoin from IM fosphenytoin administration is 100%.

Fosphenytoin is available as a solution containing 50 mg PE/mL. By labeling fosphenytoin this way, no dosing adjustments are necessary when converting from phenytoin sodium to fosphenytoin or vice versa. Although the prescriber ordered 275 mg PE, S.D. may be underdosed. His oral dosage of phenytoin suspension is providing the equivalent of 300 mg/day of sodium phenytoin. Phenytoin suspension and chewable tablets contain free acid, whereas capsules contain sodium phenytoin. Therefore, phenytoin capsule products contain only 92% of the labeled content as phenytoin acid (ie, a 100-mg sodium phenytoin capsule contains only 92 mg of phenytoin acid). He should receive a 300-mg dose of fosphenytoin daily to fully replace his current dosage of phenytoin suspension.[104]

Assuming that S.D. will be given 300 mg PE of fosphenytoin daily, he will require a total of 6 mL of this injection given IM. This medication is well tolerated when given IM, and S.D.'s full daily dose can be given in a single injection without causing excessive discomfort. Some clinicians report administering IM injections of fosphenytoin as large as 20 mL in a single site without adverse consequences or serious discomfort.[105] It is also possible to divide his daily dosage into two injections given in two different sites, although many patients prefer to receive fewer injections.

ADVERSE EFFECTS

CASE 60-5

Question 1: G.R. is a 53-year-old male with focal-onset epilepsy characterized by occasional tonic–clonic seizures. He has taken phenytoin for the past 2 years. His dosage of phenytoin was recently reduced from 400 to 360 mg/day because of symptoms of ASD intoxication (mild confusion, occasional diplopia, ataxia, and lateral gaze nystagmus). After the dose reduction, his confusion and diplopia decreased significantly. The neurologic evaluation at the lower dose was within normal limits. No seizures occurred during the subsequent 8 weeks. He continued to report being mildly "unsteady" on his feet. He also exhibits mild-to-moderate gingival hyperplasia and significant halitosis.

How should phenytoin-related gingival hyperplasia be managed? Because G.R.'s seizures are apparently under complete control, is there any problem maintaining him on his current dose of phenytoin?

Gingival hyperplasia

Gum hyperplasia related to phenytoin is common and troublesome. Prevalence is estimated at 40% to 50% of treated patients.[106] Prevalence and incidence rates, however, are misleading because the occurrence and severity of hyperplasia are related to the dose and serum concentration of phenytoin.[106,107] Gingival hyperplasia is of obvious cosmetic importance. Also, as in G.R., formation of pockets of tissue leads to difficulties with oral hygiene and halitosis may result. The mechanism of phenytoin-induced gingival hyperplasia is not well understood.[106,107]

Three approaches to the treatment of existing hyperplasia[107] are (a) dosage reduction or replacement of phenytoin with an alternative ASD, if possible, which will permit partial or complete reversal of hyperplasia; (b) surgical gingivectomy, which will correct the problem temporarily, but hyperplasia eventually recurs; and (c) periodontal treatment, which will eliminate local irritants and maintains oral hygiene. Treatment for existing hyperplasia and prevention of further tissue enlargement is important. Assuming that phenytoin is producing adequate seizure control, a combination of gingivectomy and follow-up periodontal treatment may be the best approach.

Oral hygiene programs appear to reduce the degree and severity of gingival hyperplasia when they are initiated before phenytoin therapy is started.[107] Patients who are beginning phenytoin therapy

should be educated about the role of oral hygiene in diminishing this adverse effect.

Neurotoxicity

Patients chronically maintained on intoxicating doses of phenytoin appear to be at risk for developing irreversible cerebellar damage and/or peripheral neuropathy. Cerebellar degeneration, resulting in symptoms such as dysarthria, ataxic gait, intention tremor, and muscular hypotonia, is of particular concern; this complication has been observed after episodes of acute phenytoin intoxication.[108,109] Generalized seizures also can cause cerebellar degeneration secondary to hypoxia. For this reason, the relative importance of phenytoin in the development of this condition is controversial. Nevertheless, cerebellar degeneration has been reported in several patients without hypoxic seizures.[109,110]

Symptomatic phenytoin-related peripheral neuropathy is rare, although electrophysiologic evidence of impaired neuronal conduction is found in many patients.[108,111] Symptomatic patients may report paresthesia, muscle weakness, and occasional muscle wasting. Knee and ankle tendon reflexes are absent in 18% of patients on long-term phenytoin therapy; the upper limbs are rarely affected.[112] Although areflexia may be irreversible,[112] electrophysiologic abnormalities may be closely related to excessive serum phenytoin concentrations and are reversible after dosage reduction or discontinuation.[110]

In G.R., the general discomfort of mild phenytoin intoxication and the potential for producing cerebellar degeneration necessitate a therapy alteration. The phenytoin dose should be reduced to 330 mg/day because it may produce adequate seizure control without toxic symptoms. Should seizures recur at this lower dosage, it may be advisable to consider an alternative ASD.

ANTISEIZURE DRUG IMPACT ON BONE

Some ASDs have a negative impact on bone density. People with epilepsy treated with these drugs are at increased risk for bone

disorders and fractures.[113] Longer duration of ASD therapy and exposure to multiple ASDs are thought to predict bone loss. Enzyme-inducing ASDs (carbamazepine, phenytoin, and phenobarbital) have been associated with bone loss and an increased risk for fracture. Valproate, although not an enzyme inducer, is associated with decreased bone mineral density in children.[114] Less is known about the impact of newer ASDs on bone mineral metabolism.[115] Because of the length of phenytoin use, G.R. is at risk. His bone health should be further evaluated by a dual-energy x-ray absorptiometry (DEXA) scan to examine his bone mineral density. G.R. should be evaluated for other risk factors of reduced bone health (eg, immobility, poor diet, family history). Oral calcium and vitamin D supplementation should be implemented. Depending on the outcome of evaluation, a change from phenytoin to an ASD with less or no effect on bone should be considered.

NEW-ONSET SEIZURES IN OLDER ADULTS

CASE 60-6

QUESTION 1: J.R., a 74-year-old male with newly diagnosed focal seizures, is referred to the neurology clinic for evaluation and treatment. The etiology of his new-onset seizures is presumed to be a recent cerebral infarct. His seizures are focal seizures with impaired awareness (he "blacks out" and loses track of time). He has no history of secondary generalized tonic–clonic convulsions. He has had three seizures in the last 4 weeks. His last seizure resulted in a fall down a flight of stairs. His wife reports that he is more likely to have a seizure if he gets "overtired" or "stressed-out." He is also being treated for hypertension and diabetes.

What options are available for the treatment of J.R.'s epilepsy?

There are relatively few head-to-head comparative studies of ASDs in patients with epilepsy. Even fewer studies address the comparative efficacy of ASDs in older adults. Three studies, in particular, are important when discussing ASD treatment in older adults with epilepsy.

Brodie et al[116] compared lamotrigine (*n* = 102) with carbamazepine (*n* = 48) in older adults with newly diagnosed epilepsy via a double-blind, randomized, parallel study. Discontinuation rates because of adverse effects (the primary outcome) were higher for carbamazepine (42%) than for lamotrigine (18%). Using time to first seizure as a measure of efficacy, no differences were found between the two ASDs, and the authors suggested that lamotrigine is "acceptable" as initial treatment in older adults with newly diagnosed epilepsy.

Carbamazepine (600 mg/day), gabapentin (1500 mg/day), and lamotrigine (150 mg/day) were compared for efficacy and tolerability in 593 patients older than age 55 years (mean age 72 years) with newly diagnosed epilepsy.[117] Although efficacy was similar in all three groups, study termination for adverse events varied between treatment groups. Carbamazepine had the highest termination rate (31%), followed by gabapentin (21.6%), and then lamotrigine (12.1%) (*P* = .001). The authors concluded that lamotrigine and gabapentin should be considered as initial therapy for new-onset seizures in older adults with epilepsy.

Werhahn et al[118] evaluated carbamazepine (controlled-release), lamotrigine, and levetiracetam in 359 patients age 60 years and older (mean age 71.4 years) with newly diagnosed focal epilepsy via a double-blind, randomized, multicenter trial. As with the other two studies, efficacy (as measured by seizure freedom rates) did not differ between the three drugs. But retention rate at week 58 (primary outcome) was significantly higher for levetiracetam (61.5%) than for carbamazepine (45.8%) (*P* = .02). The retention rate for lamotrigine (55.6%) was close to that of levetiracetam.

These studies in older adults with new-onset epilepsy suggest that gabapentin, lamotrigine, or levetiracetam would be good choices for initial treatment of J.R.'s epilepsy. It is noteworthy that none of these ASDs are FDA approved for newly diagnosed epilepsy.

It is also important to consider drug interaction profile, dosing frequency, and drug costs when selecting ASD therapy. Generally, older adults take more medicines than younger individuals. For example, the average number of concomitant medications in the

study by Rowan et al[117] was seven. J.R. is likely to be taking other medicines for diabetes and hypertension. Gabapentin, lamotrigine, nor levetiracetam cause drug–drug interactions, although lamotrigine is influenced more so than gabapentin or levetiracetam by other medicines. Doses of gabapentin and levetiracetam must be adjusted for renal function.

ADVERSE EFFECTS

Comparative studies identified minimal differences in efficacy. Newer ASDs, however, showed better tolerability than the older ASDs. In general, older adults not only respond to ASDs at lower doses and concentrations but they also exhibit toxicity symptoms at lower doses than do younger patients. Age-related declines in renal and hepatic function may account for those observations. The pharmacokinetics of many ASDs have been studied in older adults, and a decrease in clearance is noted as compared with the young.[119] Decreased clearance of ASDs in older adults has often been cited as a reason for their increased responsiveness to these drugs.

The impact of ASDs on cognition is an important issue for all patients with epilepsy and perhaps it is an even greater issue in older adults.[120–122] As evidenced from the study by Rowan et al,[117] CNS toxicities such as dizziness, unsteady gait, and ataxia are common adverse effects of ASDs in older adults. These symptoms may increase the risk of falls, which are of particular concern in light of the potential negative effects of ASDs on bone mineral density.

J.R. and his family should be informed about the benefits and risks associated with each ASD and they should also be incorporated into the decision-making process. ASD therapy in older adults should follow the “start low and go slow” adage, and older adults should be monitored for both efficacy (via a seizure calendar) and toxicity (reporting any intolerable adverse effects).

ABSENCE SEIZURES

Choice of Medication and Initiation of Ethosuximide Therapy

CASE 60-7

Question 1: T.D., a 7-year-old, 55.12-pound (25-kg) female, is reported by her teacher to have three or four episodes of "staring" daily. Each spell lasts 5 to 10 seconds. No convulsive movements occur during the episodes, but her eyelids appear to flutter. She is fully alert afterward. T.D.'s school performance is somewhat below average, despite an intelligence quotient (IQ) of 125. An EEG shows 3-Hertz (Hz) spike-and-wave activity. T.D. is diagnosed with typical childhood absence epilepsy. Physical examination and laboratory evaluation findings are normal, and no other positive findings are present on the neurologic examination.

What drug should be prescribed for T.D., and how should therapy with this drug be initiated?

Ethosuximide, valproate, and lamotrigine are commonly used to treat absence epilepsy in the United States. Ethosuximide and valproate are considered highly effective and preferred over lamotrigine for the treatment of childhood absence epilepsy.[123] Ethosuximide is a succinimide agent that blocks T-type calcium currents in the thalamus. The drug is effective against absence seizures but is ineffective against other seizure types. Ethosuximide is generally well tolerated. Given its lack of idiosyncratic hepatic toxicity in children, it may be preferred over valproate for the treatment of childhood absence epilepsy. Valproate, a carboxylic acid derivative, has broad-spectrum activity against many focal-onset and generalized-onset seizure types. Valproate is associated with many adverse effects that may limit use in childhood absence epilepsy. In addition to ethosuximide and valproate, lamotrigine also has been recommended as an initial monotherapy agent for treatment of absence epilepsy, although it is not FDA approved for this indication[124–126] (see Tables 60-1 and 60-5).

Valproate, ethosuximide, and lamotrigine were studied in the treatment of newly diagnosed childhood absence epilepsy.[127] The primary outcome assessed freedom from treatment failure. The rates

for valproate and ethosuximide were similar and were statistically significantly higher than lamotrigine-treated patients. Moreover, attention dysfunction was significantly more common with valproate than with ethosuximide. Valproate was also more efficacious than lamotrigine for treatment of idiopathic generalized seizures (including absence) in the Standard and New Antiepileptic Drugs (SANAD) trial.[128] Because of similar rates of efficacy and potentially more favorable adverse effect profile compared with valproate, ethosuximide is considered first line as monotherapy for childhood absence epilepsy. Valproate is more likely to cause significant nausea and initial drowsiness, and it is more likely to interact with other drugs, including ASDs. Valproate usually is reserved as a second-line therapy for patients whose absence seizures do not respond to ethosuximide.[129]

Lamotrigine is considered an alternative for patients who do not respond to the first- or second-line therapies or experience intolerable adverse effects. One-third of patients may respond favorable to a trial of lamotrigine, making it an attractive option in refractory cases. Furthermore, in select patients, a trial of a combination of valproate and lamotrigine may be considered in the event inadequate control is established with monotherapy valproate.[130] Finally, clonazepam, a benzodiazepine, may be effective for control of absence seizures as add-on therapy.[131]

Therapy with this drug is limited by prominent CNS adverse effects (sedation, ataxia, and mood changes) and development of tolerance to its antiseizure effect after long-term use.[132]

A reasonable starting agent and dose for T.D. is ethosuximide 15 to 20 mg/kg/day by mouth divided twice daily. The child should be assessed for tolerability of swallowing capsules. Ethosuximide is available in 250-mg capsules and a commercially available oral solution at a concentration of 250 mg/5 mL. The oral solution may allow for ease of titration in this patient if additional seizure control is needed. With either formulation, T.D. can start at a dose of ethosuximide 250 mg by mouth twice daily. The dose can be increased by 10 mg/kg/day or 250 mg/day for T.D., every 10 to 14 days as necessary to control seizures. The average half-life of

ethosuximide in children is ~30 hours, which would require 7 days to achieve steady state in the blood. Delaying dose adjustments by 10 to 14 days allows the drug to reach steady state and additional time to assess the response to therapy after steady state is achieved.[34]

THERAPEUTIC MONITORING

Case 60-7, Question 2: What subjective or objective clinical data should be monitored in T.D. for evidence of therapeutic and adverse effects of ethosuximide?

T.D.'s seizure frequency and any adverse effects are the primary monitoring parameters. The usual target range for ethosuximide serum concentrations is 40 to 100 µg/mL; however, a clearly defined toxicity syndrome does not reliably develop when serum concentrations exceed 100 µg/mL. Although ethosuximide traditionally is administered in divided doses, its long half-life may allow for daily administration in patients who tolerate it well. Clinicians should be alert to acute adverse effects of nausea and vomiting that are associated with large single doses of ethosuximide; should these occur, divided daily doses may be necessary.[34]

Ethosuximide causes neutropenia in ~7% of patients. Rarely patients may exhibit fatal pancytopenia, even upon discontinuation of the drug. Laboratory monitoring for idiosyncratic hematologic toxicity from ethosuximide often is recommended by checking a periodic CBC.[133] These hematologic reactions, however, can occur unpredictably at any time during therapy and often are missed by routine laboratory monitoring. Patient or caregiver education regarding signs and symptoms associated with leukopenia and pancytopenia (eg, sudden onset of severe sore throat with oral lesions, easy bruising, increased bleeding tendency) may be more important than laboratory monitoring.[56]

PATIENT OR CAREGIVER EDUCATION

T.D. and her parents should be counseled on the importance of good adherence to the prescribed regimen. Rapid discontinuation of ASDs (often secondary to nonadherence) may precipitate SE. The family should also be educated on the idea that antiseizure medication controls but does not cure the seizure disorder. The family should also be informed of the expectation for response to therapy, including time to achieve stable blood levels as well as potential for dose increases. T.D.'s parents should be educated on typical adverse effects such as nausea and sedation. Tolerance to these effects usually develops, although temporary dose reductions may be necessary.

GENERALIZED TONIC–CLONIC SEIZURES ACCOMPANYING ABSENCE SEIZURES

CASE 60-7, QUESTION 3: Three months later, T.D. experiences an average of one absence seizure every 2 weeks. She is currently receiving ethosuximide 750 mg/day. Her initial drowsiness has almost disappeared, and nausea was alleviated by administering doses with food. She has, however, experienced two tonic–clonic convulsions in the past month. Both seizures were witnessed by her parents and were well described. No auras or signs of focal seizure activity were apparent, and each episode consisted of typical tonic–clonic activity lasting 1 to 2 minutes. T.D. was incontinent of urine on both occasions, and postictal confusion and drowsiness were significant. Physical examination and laboratory testing showed no abnormalities. A repeat EEG continued to show infrequent 3-Hz spike-and-wave discharges; no abnormal focal discharges were noted. What is the relationship between T.D.'s tonic–clonic seizures and ethosuximide therapy?

It is commonly believed, and often stated in the literature, that ethosuximide may precipitate or worsen tonic–clonic seizures; however, this effect has not been clearly demonstrated. As many as 50% of patients who initially present with absence seizures also experience tonic–clonic seizures.[134] Historically, another ASD (eg, phenobarbital or phenytoin) was added to ethosuximide therapy to

prevent tonic–clonic seizures.[135] However, routine use of drugs for prophylaxis of tonic–clonic seizures may increase the risk of toxicity and potentially reduce adherence with medication regimens. Sedative drugs, especially phenobarbital, actually may aggravate absence seizures in some patients.[136]

Assessment Regarding Need for Alteration in Antiseizure Drug Therapy and Choice of Alternative Antiseizure Drug

Case 60-7, Question 4: What alterations are indicated in T.D.'s drug therapy because of the appearance of generalized tonic–clonic seizures?

Drug therapy for prevention of tonic–clonic seizures is indicated. Phenytoin, carbamazepine, or valproate might be considered for use in T.D. Owing to her age and sex, many clinicians would avoid using phenytoin because of its dysmorphic and cosmetic adverse effects. Carbamazepine is widely used for secondary generalized tonic–clonic seizures and some cases of tonic–clonic seizures in children. It lacks many of the troublesome, common adverse effects associated with phenytoin. Carbamazepine, however, is not effective for control of absence seizures. Therefore, it is likely that both ethosuximide and carbamazepine would be needed by T.D. Additionally, carbamazepine may exacerbate absence seizures in children with mixed seizure disorders.[137,138] The need for polytherapy and the possible risk of seizure exacerbation make carbamazepine a less attractive treatment option for T.D.

Valproate is effective for controlling both absence and primary generalized tonic–clonic seizures.[42,50] T.D. appears to have primary generalized tonic–clonic convulsions; focal signs (eg, unilateral or single limb involvement) were not observed, and focal discharges (eg, isolated abnormal electrical activity localized to one portion of the brain) were not found on the EEG. Although neither observation completely rules out secondary generalized tonic–clonic seizures,

the likelihood seems low. Therefore, valproate may offer advantages over carbamazepine in terms of efficacy. In addition, both of T.D.'s seizure types potentially could be controlled with a single medication.

Valproate Therapy

INITIATION AND DOSAGE

Case 60-7, Question 5: T.D.'s physician elects to start valproate and discontinue ethosuximide. The goal is to control both seizure types with valproate alone. What process should be used to discontinue ethosuximide and initiate valproate?

Techniques used by clinicians to substitute one ASD for another depend largely on experience and clinical judgment. Generally, it is best to attain a potentially therapeutic dose of a new medication before attempting to discontinue the previous drug. Ethosuximide has a relatively long half-life, whereas valproate has a short half-life. Steady-state serum concentrations of valproate can be established and evaluated rapidly. Evaluation of the effect of decreases in the ethosuximide dose will take longer because of the prolonged elimination. Once a desired valproate dose or serum concentration has been achieved, the ethosuximide dose can be reduced gradually by 250 mg/day every 2 to 4 weeks.

Valproate should be initiated at a dose of 10 to 15 mg/kg/day divided twice daily. A reasonable starting dose for T.D. is 125 to 250 mg twice daily. Valproic acid syrup or capsules or divalproex sodium can be used. Divalproex often is preferred because it may cause fewer GI adverse effects than valproic acid. Syrup forms of valproate probably should be avoided unless extremely small doses are required (eg, for infants) or the patient cannot swallow capsules. Valproate syrup has an unpleasant taste, and its rapid absorption increases the likelihood of acute, dose-related adverse effects such as nausea. Lower initial valproate doses are less likely to cause acute adverse effects (eg, drowsiness and GI upset). Weekly dose increases of 5 to 10 mg/kg/day usually are well tolerated and would

be appropriate for T.D. More rapid increases may be desirable if tonic–clonic seizures occur frequently. The maximal recommended dosage of valproate is 60 mg/kg/day. Many patients, especially those receiving enzyme-inducing drugs, require higher-than-recommended doses to achieve adequate clinical effect; other patients may respond at much lower doses. Valproate can be titrated in T.D. to a target serum concentration of 50 to 100 µg/mL. Once ethosuximide is withdrawn, the valproate dose can be further adjusted on the basis of seizure frequency and adverse effects.

DOSAGE FORMS

Case 60-7, Question 6: T.D. has been taking valproic acid capsules, 250 mg tid, for 3 weeks. Ethosuximide was discontinued 2 weeks ago. At that time, a valproate serum level just before her morning dose was 68 µg/mL. She has not experienced generalized tonic–clonic seizures for 6 weeks but continues to have an absence seizure every 2 to 3 weeks. T.D. reports nausea, epigastric burning pain, and occasional vomiting lasting ~1 hour after her doses of valproate. All recent laboratory tests were within normal limits. Administration of the drug with meals is only partially helpful. What alterations can be made in T.D.'s dosing regimen to relieve these symptoms and possibly improve seizure control?

T.D. appears to be a candidate for the use of an enteric-coated valproate preparation or extended-release divalproex. Divalproex tablets are available as an enteric-coated delayed-release preparation, which causes delayed rather than extended absorption of valproate; therefore, these tablets are not a sustained-release product formulation. When patients are switched from nonenteric-coated formulations to divalproex tablets, the frequency of administration should not be decreased. Valproic acid and enteric-coated dosage forms of valproic acid or divalproex are completely absorbed so they can be interconverted at the same total daily dose of medication.[139,140] An extended-release formulation of divalproex sodium is also available that can be administered as a single daily dose. Extended-release divalproex (divalproex ER), however, is not bioequivalent to other dosage forms of valproate.[141] The

manufacturer recommends a dose increase of 8% to 20% when patients are converted to divalproex ER from other forms of valproate. T.D.'s valproic acid capsules can be replaced with an equal daily dose of divalproex tablets to attempt to alleviate the GI disturbances. Divalproex should be administered three times daily. Alternatively, T.D. could be given 1000 mg of divalproex ER once daily. T.D. should see relief from GI adverse effects within a week of the therapy change. Furthermore, if the GI upset resolves, the dose of divalproex can be increased in an effort to improve seizure control.

Capsules containing enteric-coated beads of divalproex also are available; the 125-mg capsule contents can be dispersed in food for administration to children or others who have difficulty swallowing tablets or capsules. In addition, use of the "cap" end of the capsule to measure half of the contents can approximate doses of 62.5 mg.

PHARMACOKINETICS AND SERUM CONCENTRATION MONITORING

Case 60-7, Question 7: Two weeks later, T.D. returns for follow-up. Her GI symptoms have resolved. She has been taking divalproex tablets 250 mg with breakfast and lunch and 375 mg with a bedtime snack for the past week. She has had no seizures in the past 2 weeks and no adverse effects. A valproate serum level before her morning dose today was 117 µg/mL (recall her previous valproate level of 68 µg/mL). The laboratory reports that duplicate determinations of this level agreed within 5 µg/mL. T.D. and her parents are able to correctly state the instructions and the tablet count in her prescription bottle is correct. She denies other medication use. How can this disproportionate increase in her valproate serum concentration be explained, and what is the clinical significance? Does valproate exhibit dose-dependent pharmacokinetics?

The observed changes in T.D.'s valproate serum concentrations are probably not the result of dose-dependent metabolism as is seen with phenytoin. Instead, these changes are more readily explained by the absorption characteristics of divalproex tablets. Peak serum concentrations of valproate after administration of divalproex may be

delayed for 3 to 8 hours, and administration of food may further delay absorption.[142] In addition, diurnal fluctuation in both the rate and extent of absorption of divalproex may be significant. Absorption may be reduced by approximately one-third, and peak plasma concentrations may be delayed for up to 12 hours for divalproex doses administered in the evening.[35] Twelve to 15 hours probably elapsed between the administration of T.D.'s last dose and blood sampling; therefore, the currently reported blood level may more closely approximate a peak concentration than a trough concentration. Previous blood levels, determined while she was receiving immediate-release valproic acid capsules, are more likely to have been trough concentrations. Another explanation is that T.D.'s adherence to her prescribed regimen also may have increased because of the change in dosage form and reduced adverse effects.

Other pharmacokinetic factors may have actually moderated this unusual increase in valproate concentrations. Valproate concentrations may fluctuate throughout the day in a pattern that does not reflect the timing of doses.[143] This fluctuation may be partially related to changes in serum concentrations of endogenous fatty acids that displace valproate from protein-binding sites. Valproate's hepatic clearance is restrictive (ie, valproate has a low extraction ratio, and its clearance is limited by the free fraction of drug in plasma). Therefore, when valproate is displaced from protein-binding sites, the free fraction of drug in the plasma increases and subsequently the clearance increases. As a result, free serum concentrations of valproate increase only transiently, whereas total serum concentrations decrease. Valproate also exhibits dose dependency in its binding to serum proteins. As the serum concentration approaches 70 to 80 μg/mL, binding sites on albumin molecules become saturated, and the free fraction of drug in the plasma increases.[34,139] Considering the extensive variability in serum concentrations, serum valproate concentrations may not be particularly useful to guide therapeutic decisions.[137]

The clinical significance of T.D.'s elevated valproate serum concentrations is minimal. She is not experiencing symptoms suggestive of valproate toxicity, and it is too soon after the dosage

increase to assess the effect of this change on her seizure frequency. Therefore, alteration in her drug therapy is unnecessary at present and might only confuse evaluation of her response to this drug. She should be observed for an additional 4 to 6 weeks to evaluate seizure frequency before further alterations in her dosing regimen are considered. Further increases in her dosage are not contraindicated as long as she is tolerating the medication and requires additional seizure control.

HEPATOTOXICITY

Case 60-7, Question 8: Two months later, T.D. is taking 375 mg of divalproex tid with meals. She has had no absence seizures for 5 weeks and no generalized tonic–clonic seizures for 10 weeks. Yesterday, her valproate plasma concentration was 132 μg/mL. In addition, her alanine aminotransferase (ALT) was 32 international units/mL, and her aspartate aminotransferase (AST) was 41 international units/mL. All other laboratory tests (bilirubin, alkaline phosphatase, lactate dehydrogenase, prothrombin time, and serum albumin) were normal. T.D.'s LFTs have been monitored monthly since she began taking valproate, and they were previously normal. Physical examination was negative for scleral icterus, abdominal pain, or other signs of liver disease. What is the most appropriate approach to manage elevated liver enzymes caused by valproate therapy in T.D.?

Liver damage related to valproate therapy appears to be caused by accumulation of hepatotoxic metabolites of valproate (probably 4-en-valproate) in certain patients.[144,145] These metabolites may be formed in larger quantities in patients who also receive enzyme-inducing drugs such as phenobarbital. Most cases of fatal hepatotoxicity have occurred in young (age <2 years) patients with neurologic and metabolic abnormalities who also had severe, difficult-to-control seizures and who were taking multiple ASDs.[144–149] It is important to recognize, however, that severe hepatotoxicity is not limited to this population.[150] Liver damage occurs early in therapy and symptomatically resembles fulminant hepatitis with hepatic failure. Patients may experience vomiting, drowsiness, lethargy, anorexia, edema, and jaundice, which often precede laboratory

evidence of hepatic damage. Liver biopsies in affected patients show evidence of hepatic necrosis and steatosis. Death results from hepatic failure or a Reye-like syndrome.[145,147,151]

Asymptomatic elevations in liver enzymes (such as those found in T.D.) occur commonly during the first 6 months of treatment with valproate and usually are not associated with severe or potentially fatal valproate-induced hepatotoxicity. These changes in aminotransferase usually disappear without alteration in therapy; in some cases, temporary dosage reduction is followed by normalization of laboratory tests within 4 to 6 weeks.[145,147] Without systemic symptoms or other signs of significant liver damage, it is unlikely that the laboratory abnormalities observed in T.D. represent severe liver toxicity from valproate. Because T.D. is responding well to valproate therapy, no change in therapy is warranted at this time. Laboratory testing probably can be repeated in 4 to 6 weeks. T.D. and her family should be educated regarding the possible signs and symptoms of valproate-induced liver damage and instructed to consult their physician if T.D. experiences these symptoms.

Routine liver function tests

Case 60-7, Question 9: What is the usefulness of routinely monitoring LFTs in patients receiving valproate?

Serious hepatotoxicity related to valproate therapy is extremely rare. Historically, the rate of fatal hepatotoxicity decreased significantly (despite substantial increases in the use of valproate) after the use of the drug in high-risk patients (eg, the very young) decreased and its use as monotherapy increased. Hepatotoxicity is estimated to occur in <0.002% of patients treated with valproate.[145,146,148] In children younger than age 2 years who receive ASD polytherapy, the incidence of this complication is 1 in 500 to 1 in 800. Because asymptomatic, apparently benign elevations in liver enzymes are common early in therapy with valproate and symptoms of liver damage often precede laboratory changes, frequent LFTs

during early valproate therapy are unlikely to detect serious hepatotoxicity.[56,145–147,152] Education of caregivers or patients regarding potential symptoms of hepatotoxicity, with careful observation and follow-up by health care professionals, is recommended as the most effective method to monitor for this drug-induced illness.

In patients with risk factors for hepatotoxicity (ie, very young children with associated neurologic abnormalities and those receiving polytherapy), increases in LFT values that are noted early in therapy may be clinically significant. At the onset of symptoms suggesting this condition, laboratory testing may help early detection of hepatotoxicity.

ACUTE REPETITIVE (CLUSTER) SEIZURES

Rectal Diazepam Gel

CASE 60-8

QUESTION 1: B.N., a 7-year-old, 61.73-pound (28-kg) male, has had seizures since age 3 months. He suffered anoxia at birth. His seizures usually involve initial confusion and disorientation, followed by generalized tonic–clonic convulsive activity. Despite treatment with carbamazepine at maximal tolerated doses and serum concentrations (300 mg tid; 9–11 µg/mL), he continues to have approximately two seizures monthly. Recent trials of topiramate and tiagabine as additions to his carbamazepine were unsuccessful and caused intolerable sedation and lethargy. During the past year, he has been admitted to the emergency department (ED) five times because of seizure "flurries" consisting of three to six seizures occurring during a period of 12 or fewer hours. Although he regains consciousness between these "flurry" seizures, he remains lethargic. During ED admissions, IV diazepam was administered. This was rapidly successful in terminating seizure activity. B.N.'s mother relates that she usually can identify the onset of seizure flurries; B.N.'s behavior changes, and he becomes "clingy," "whiny," and hyperactive. She also indicates that the initial seizure in a flurry differs from B.N.'s typical episodes. Before the onset of generalized seizure activity, he experiences much briefer periods of confusion.

In addition, the generalized seizures are longer and more severe (often with dramatic cyanosis) at the beginning of a "flurry."

Why is prophylactic or abortive therapy for B.N.'s seizure flurries indicated? What factors about B.N. predict successful use of such treatment, and how can it be administered?

Frequent ED visits resulting from cluster seizures are expensive and frightening for many patients and their families. B.N. continues to experience seizure flurries despite carbamazepine therapy. He responds well to IV diazepam and has a caregiver who can identify the onset of seizure clusters. His seizure clusters appear to be distinct from the other seizures that he experiences. All of these factors indicate that a trial of caregiver-administered treatment to abort these cluster episodes is likely to be helpful and should be initiated.

Rectal diazepam gel is available for home administration to patients with acute episodes of repetitive seizure activity.[153] When diazepam gel is administered rectally, peak plasma concentrations occur in ~1.5 hours,[154] and cluster seizures are often terminated within 15 minutes. Use of diazepam rectal gel is recommended only when caregivers can recognize the onset of cluster seizures, which are different from a patient's usual seizure activity. The caregivers should be trained to administer the preparation safely and to monitor the patient's response (eg, respiratory status) after administration. Caregivers should be informed that this preparation is not for as needed use with every seizure; it should be used only for identifiable cluster seizures or prolonged seizures.

B.N.'s mother should administer rectal diazepam gel at the onset of identifiable cluster seizure activity. A dose of ~0.3 mg/kg (10 mg in this patient) should be given and repeated, if necessary, within 4 to 12 hours of the first dose. B.N.'s mother should be counseled on the administration of this product and given the patient package insert, which gives complete instructions for the administration of rectal diazepam. After administration, B.N. should be monitored for at least 4 hours to ensure that no respiratory depression or other adverse effects are occurring and to assess the effect of the medication on

his seizures. The most common adverse effect seen with rectal diazepam is somnolence, occasionally accompanied by dizziness and ataxia. Respiratory depression is very uncommon.

A commercially available intranasal formulation of midazolam was approved in 2019 for use in seizure clusters.[155] Dosing and FDA approval limit the use of this formulation in children younger than age 12 years. A compounded version has been used for many years in management of cluster seizures. Some potential benefits of intranasal midazolam, regardless of formulation, over rectal diazepam may include increased social acceptability and ease of administration, improved absorption and seizure control, and less adverse effects.[156,157] Other IM, buccal, and intranasal formulations of benzodiazepines are currently being investigated for their utility in aborting cluster seizures.[158]

FEBRILE SEIZURES

Incidence and Classification

CASE 60-9

QUESTION 1: J.J., a 14-month-old female, is brought to the ED after having a generalized tonic–clonic convulsion lasting ~5 minutes. The episode occurred in association with an upper respiratory infection. On arrival in the ED, her rectal temperature was 103.1 °F (39.5 °C). She was alert at that time. All laboratory and neurologic findings, including lumbar puncture, were normal. J.J. has no history of neurologic abnormality. Her 7-year-old brother suffers from both absence and generalized tonic–clonic seizures.

What is the relationship between febrile seizures and epilepsy? How may J.J.'s convulsion be classified on the basis of the data available?

Up to 8% of children have a febrile seizure between ages 6 months and 6 years.[159,160] Simple febrile seizures occur with a fever of ≥100.4 °F (38 °C) in previously normal children younger than age 5 years. They last <15 minutes and have no focal features. The

associated seizure does not arise from CNS pathology. Complex febrile seizures show focal characteristics, lasts longer than 15 minutes, or has recurrence within 24 hours. The child may or may not have previous neurologic abnormalities. The risk of experiencing an unprovoked afebrile seizure after a febrile seizure is four times greater than in the general population. Risk factors for the development of chronic epilepsy include a family history of afebrile seizures, complex febrile seizures, and pre-existing neurologic abnormality.[159,160]

J.J.'s seizure appears to be a simple febrile seizure that developed in association with her upper respiratory tract infection. The lack of previous neurologic abnormality and normal findings on lumbar puncture and laboratory evaluation help confirm this assessment.

Treatment of Acute Seizure

Case 60-9, Question 2: How should J.J.'s febrile seizures be treated?

Because J.J. is not having a seizure at present, ASD therapy is not required. Measures to reduce her elevated temperature should be initiated; however, these measures may not reduce the risk of further seizures. Acetaminophen and tepid sponge baths usually are helpful.

If patients experience prolonged or recurrent febrile seizures, either diazepam or, less commonly, midazolam may be administered.[160–162] Rectal diazepam gel can be used for this purpose.

Prophylaxis and Choice of Antiseizure Drug

Case 60-9, Question 3: On the basis of the subjective and objective data available for J.J., is ASD therapy indicated on a long-term basis? What are the benefits and risks of ASD prophylaxis for febrile seizures?

Long-term treatment or prophylaxis with an ASD for simple febrile seizures is not recommended. Up to 54% of affected patients will have recurrent febrile seizures, and the risk of recurrence is even greater when the first episode occurs before age 13 months. Nonetheless, recurrent febrile seizures are not associated with brain damage or development of epilepsy.[159] Although administration of continuous ASD treatment may reduce the recurrence rate of febrile seizures, published guidelines recommend against this practice because of the associated adverse effects of medication use.[163]

Prophylactic administration of various fast-acting agents, given during fever episodes, has been studied as an alternative to continuous treatment for the prevention of febrile seizures. Agents in both the ASD and antipyretic drug classes have been studied in this regard, but no clinically important benefits have been found.[164–168] Thus, ASD prophylaxis for febrile seizures is probably not warranted for J.J., even though she is at risk for both development of epilepsy and recurrence of febrile seizures. Currently, evidence does not suggest that medication will reduce the likelihood of developing epilepsy. Close medical follow-up of J.J. is warranted. Her parents should be counseled to contact a physician if J.J.'s febrile seizure is accompanied by focal features or last longer than 15 minutes; or, if J.J. experiences afebrile seizures. Antipyretic medications may be administered for comfort measures during febrile illnesses, but there is no evidence to support that the administration of antipyretics reduces the occurrence of future febrile seizures.

SKIN RASH: HYPERSENSITIVITY REACTIONS TO ANTISEIZURE DRUGS

CASE 60-10

QUESTION 1: R.S., a 34-year-old male, has been taking phenytoin 200 mg bid for the past 7 weeks to control focal seizures with impaired awareness and secondary generalized tonic–clonic seizures. Seizures began ~4 months ago

after surgical evacuation of a subdural hematoma. Today, he appears at the walk-in clinic with an “itchy rash” that began 2 days ago. He describes “feeling lousy” for the past week. On examination, he is febrile (101.3 °F [38.5 °C] orally). A maculopapular, scaly, erythematous rash covers his upper extremities and torso, and the mucous membranes of his mouth appear to be mildly inflamed. Cervical lymphadenopathy is noted, and the liver is found to be enlarged and tender. R.S. also relates that his urine has become very dark in the past 2 days and that his stools are light colored.

What is the significance of R.S.’s skin rash and other signs and symptoms? Are these likely to be related to his phenytoin therapy?

Skin-related adverse reactions (eg, rash, urticarial) are relatively common (2%–3% of patients) adverse effects related to ASD therapy. Skin rash is most commonly associated with phenytoin, lamotrigine, carbamazepine, and phenobarbital. Most cases are relatively mild, but severely affected patients may exhibit Stevens–Johnson syndrome or a systemic hypersensitivity syndrome accompanied by severe hepatic damage. In R.S.’s case, signs and symptoms suggesting hepatic involvement accompany the skin rash. Fever, lymphadenopathy, and apparent inflammation of mucous membranes also suggest a hypersensitivity reaction to phenytoin with multisystem involvement and the potential for progression to Stevens–Johnson syndrome. Viral infection (eg, hepatitis, influenza, infectious mononucleosis) should be considered and ruled out as a possible cause of R.S.’s symptoms before they are attributed to phenytoin therapy.[169–172]

DRESS syndrome is a type of hypersensitivity syndrome that can occur with some drugs, including phenytoin and other ASDs, that is most commonly seen in adults. Typically, patients with this syndrome present with fever, skin rash, and lymphadenopathy during the first 2 months of ASD therapy. Hepatomegaly, splenomegaly, jaundice, or bleeding manifestations may occur. Laboratory manifestations often include leukocytosis with eosinophilia, elevated serum bilirubin, and elevated AST and ALT. When a phenytoin hypersensitivity reaction includes significant hepatotoxicity, fatality may occur in as many as 38% of affected patients.[169]

A high likelihood exists that R.S. has developed a severe reaction to phenytoin; the clinical manifestations and the timing of their appearance are typical of this reaction. Phenytoin should be discontinued immediately pending diagnostic clarification. R.S. should be hospitalized for evaluation of other possible causes of his symptoms such as viral illness and treatment. Treatment of phenytoin-related hypersensitivity and hepatotoxicity is symptomatic and supportive. Intensive therapy with corticosteroids has commonly been used, although little objective evidence exists for beneficial effects of this treatment. Potential complications of this reaction include sepsis and hepatic failure; these conditions should be treated specifically.

CASE 60-10, QUESTION 2: R.S. was hospitalized and treated with oral prednisone and topical corticosteroids. Other potential causes for his condition were ruled out, and his signs and symptoms were attributed to cutaneous and systemic phenytoin hypersensitivity. His fever resolved within 5 days; the skin rash became exfoliative but resolved without infectious complications. Laboratory parameters began to normalize after 10 days. While he was hospitalized, R.S. experienced three generalized tonic–clonic seizures that were treated acutely with administration of IV lorazepam. R.S. was afebrile at the time these episodes occurred. What information regarding the pathogenesis of phenytoin hypersensitivity and hepatotoxicity can be used to guide selection of an alternative ASD for R.S.?

Further administration of phenytoin to R.S. is contraindicated on the basis of his history of a severe hypersensitivity reaction to this drug. Although the mechanism of this reaction is not fully understood, research implicates reactive arene oxide metabolites of phenytoin (and other chemically similar ASDs) as possible causative agents for hypersensitivity reactions. Affected patients purportedly are predisposed genetically to the development of hypersensitivity, possibly because a relative deficiency of epoxide hydrolase enzymes allows the accumulation of toxic concentrations of reactive epoxide metabolites. These metabolites are believed to exert a direct cytotoxic effect and to interact with cellular macromolecules, thereby functioning as haptens that stimulate an immunologic reaction.[173,174]

Carbamazepine, phenytoin, and phenobarbital all are metabolized by similar pathways and converted to reactive arene oxides. It is hypothesized that carbamazepine-induced liver damage also may result from the effects of accumulation of reactive epoxide metabolites; these reactive metabolites differ from the 10,11-epoxide metabolite that accumulates during carbamazepine therapy. For this reason, these drugs potentially cross-react in susceptible patients. Cases of apparent cross-reactivity between phenytoin and phenobarbital or carbamazepine have been documented.[175–177] In addition, both carbamazepine and phenobarbital can produce hypersensitivity reactions similar to those seen with phenytoin. This potential for cross-reactivity should be considered when an alternative ASD is selected for R.S. An analysis of cases of ASD-related skin rashes found that the most significant nondrug predictor of skin rash was the occurrence of a rash with another ASD.[178]

Valproate has been suggested as the preferred alternative ASD for patients who have exhibited hypersensitivity reactions to phenytoin.[176] Valproate is not metabolized to arene oxides and also is chemically dissimilar to all other ASDs. Because valproate often shows good efficacy for focal seizures with impaired awareness with secondary generalization, it would seem to be a safe and potentially effective alternative ASD for R.S. Of the newer ASDs, lamotrigine should probably be avoided in R.S. because of its likelihood of causing skin rash and apparent hypersensitivity reactions. Oxcarbazepine is potentially an alternative ASD for R.S. because it is not metabolized through the arene oxide pathway. Nevertheless, 25% to 30% of patients who experience a rash in response to carbamazepine will also experience a rash with oxcarbazepine.[179] Therefore, many clinicians would avoid oxcarbazepine. Gabapentin, lacosamide, levetiracetam, pregabalin, tiagabine, topiramate, or zonisamide could be considered as alternative medications for R.S. These medications appear less likely to cause skin rash or hypersensitivity reactions.[178,180]

It is recommended that R.S. be advised to add phenytoin to his list of medication allergies.

Additional recognized genetic risk factors for ASD-related hypersensitivity reactions in specific populations are presented in Table 60-5.

OTHER THERAPEUTIC CONSIDERATIONS

Although epilepsy affects males and females equally, many health issues are of specific importance to females, such as contraceptive interactions with ASDs, teratogenicity, pharmacokinetic changes during pregnancy, breast-feeding, menstrual cycle influences on seizure activity (catamenial epilepsy), ASD impact on bone, and sexual dysfunction.[181,182] It is noteworthy that the latter two issues can also occur in males. A great need exists to educate both health care professionals and patients about the many complex issues facing females with epilepsy.[183]

For females of childbearing potential, prepregnancy planning and counseling are important, because significant ASD exposure of the fetus often occurs by the time pregnancy is known. Furthermore, some ASDs interact with contraceptive medications that can increase the risk for an unplanned pregnancy. Prepregnancy counseling also should include the importance of medication adherence to prevent seizure occurrence during pregnancy. Patients should also be informed about the risk of teratogenicity and the importance of prenatal care, including the daily supplementation of 0.4 mg of folic acid to prevent neural tube defects.

Although complete seizure control is desirable for all patients with epilepsy, adequate seizure control for a female planning to become pregnant is especially important. Falls and anoxia associated with uncontrolled generalized tonic–clonic seizures may increase the risk to the unborn baby. Monotherapy is preferred whenever possible, because the relative risk of birth defects dramatically increases with ASD polytherapy.[184,185] The ASD should be given at the lowest effective dose to reduce the possibility of birth defects.[163] Gradual

discontinuation of ASD before pregnancy may be considered if a female has been seizure-free for 2 years or longer.

Antiseizure Drug–Oral Contraceptive Interaction

CASE 60-11

Question 1: P.Z., a 26-year-old female, experiences focal seizures with impaired awareness and secondary generalized tonic–clonic seizures. She is taking phenytoin 400 mg/day and divalproex 2000 mg/day. She reports having two or three focal seizures and one generalized seizure every 3 to 4 months. Despite taking Lo/Ovral® (norgestrel 0.3 mg with ethinylestradiol 30 µg), she has just learned she is pregnant. Her last menstrual period was 6 weeks ago.

What is the relationship between P.Z.'s apparent contraceptive failure and her ASD therapy?

There have been several reports of reduced efficacy of oral contraceptives in patients receiving various ASDs.[186,187] These reports describe both breakthrough bleeding and pregnancy. Phenobarbital, phenytoin, carbamazepine, oxcarbazepine, eslicarbazepine, perampanel, and felbamate have been shown to increase the metabolism of ethinylestradiol and progestogens.[188] This effect is not associated with valproate, lamotrigine, gabapentin, tiagabine, zonisamide, levetiracetam, lacosamide, or pregabalin.[188] Topiramate in polytherapy and at high dosages (200–800 mg/day) appears to have a mild, though measurable, effect on oral contraceptive pharmacokinetics; apparent clearance of the estrogen component of combined oral contraceptives is increased in patients taking topiramate.[189] In contrast, topiramate monotherapy in lower dosages (50–200 mg/day) has a lesser impact on the pharmacokinetics of the oral contraceptive.[190]

A lack of contraceptive efficacy may present as irregular or breakthrough menstrual bleeding. Decreased efficacy is not always associated with breakthrough bleeding, however. Oral contraceptive doses can be increased to compensate for the effect of an ASD.[191] However, estrogens also may exacerbate seizures in some

females.[192] Furthermore, females older than 35 years of age and those who smoke must consider the risk of thromboembolic complications associated with higher doses of contraceptives. A second contraceptive method (eg, condoms, intrauterine devices, or spermicide) is recommended to avoid contraceptive failure.[178] Tubal ligation is also an alternative. An additional alternative that could be considered is injectable depot medroxyprogesterone acetate. Although there is a lack of clinical studies substantiating its effectiveness in patients on enzyme-inducing ASD, the pharmacokinetic characteristics of this agent suggest that its effect is not reduced by enzyme induction. Medroxyprogesterone is a high-clearance drug; its clearance is directly dependent on hepatic blood flow. Thus, enzyme induction would have little effect on the metabolism of this drug when it is administered by injection. Depot medroxyprogesterone acetate may, however, have other negative effects that would limit its choice as an alternative contraceptive in this situation.[193]

Assuming P.Z. was taking her contraceptive pills on a regular basis, it is possible that the enzyme-inducing effects of phenytoin is responsible for the reduced efficacy. Patients receiving enzyme-inducing ASD should be prospectively informed that this interaction can occur and advised concerning the use of alternative contraceptives (see Chapter 47, Contraception).

Interestingly, the estrogen component in oral contraceptives increases the clearance of lamotrigine. Lamotrigine clearance may increase twofold with concomitant use of hormonal contraceptives and decrease by 50% when the hormonal contraceptive is discontinued. Changes in lamotrigine levels associated with initiation and discontinuation of hormonal contraceptives can result in increased seizure activity in some patients and toxicity in others.[194]

Teratogenicity

Case 60-11, Question 2: What are the risks of teratogenic effects from P.Z.'s medications? What steps might be taken to minimize these risks?

P.Z.'s child is at risk of congenital malformations because of exposure to several potentially teratogenic drugs: estrogen–progestin combination oral contraceptives, valproate, and phenytoin (also see Chapter 49, Obstetric Drug Therapy).

Many ASDs have teratogenic effects.[195] Animal data regarding the teratogenic potential of the new ASDs are encouraging, but there is limited evidence in pregnant females at this time. A useful resource for clinicians is the American Epilepsy Society and the American Academy of Neurology (AAN) Practice Parameter series on management of females of childbearing potential and pregnant females with epilepsy. The series provides evidence-based recommendations in obstetric complications and change in seizure frequency; teratogenesis and perinatal outcomes, vitamin K and folic acid supplementation, and breast-feeding.[196–198] A major challenge in managing females with epilepsy in pregnancy is balancing the risk of harm to the unborn fetus with ASD exposure and/or seizure occurrence.

Assessing the risk for teratogenicity from ASDs in pregnancy is challenging, especially when multiple ASDs are used to control seizures. Several ASDs are associated with congenital malformations when administered alone. Meador et al provide data from 333 pregnancies in females with epilepsy taking an ASD monotherapy in the Neurodevelopmental Effects of Antiepileptic Drugs (NEAD) study.[199] Serious adverse outcomes (major malformations and fetal death) were significantly more likely to occur with exposure to valproate (20.3%) than with carbamazepine (8.2%), phenytoin (10.7%), or lamotrigine (1%). In addition to physical malformations, ASD exposure in utero may have an adverse effect on neurodevelopment.[200] The NEAD study found that valproate-exposed children had significantly lower IQ scores at age 6 years (mean 97) compared with children exposed to carbamazepine (mean 105), phenytoin (mean 108), and lamotrigine (mean 108) monotherapy, even after controlling for the mother's IQ and seizure type.[201] As such, when possible, valproate should be avoided in females of childbearing potential.[202]

Several strategies can be used to reduce the potential adverse effects of ASDs on pregnancy outcomes. If feasible, before conception, seizure control should be optimized using the ASD of first choice for the prospective mother's seizure type or epilepsy syndrome. Monotherapy at the lowest effective dose is the goal. Maintenance of adequate folic acid stores before conception and during fetal organogenesis is also important. Folic acid supplementation can reduce the risk of congenital neural tube malformations in infants in the general population. The American College of Obstetrics and Gynecology recommends supplementation of folic acid at 4 mg/day in females who are receiving ASD that increase the risk of neural tube defects.[203] Currently, no evidence suggests that folate supplementation reduces potential teratogenic effects of ASD nor is there an established dose for patients who are taking ASDs. Nevertheless, there is no risk of harm and standard supplementation of folic acid of at least 0.4 mg/day is recommended.[198] Because about half of pregnancies are unplanned and not evident until weeks after conception, folate supplementation should be given routinely to females of childbearing age with epilepsy. It is reasonable to consider 4 mg of folic acid supplementation daily in P.Z. because she is using valproic acid.

Physiologic changes in pregnant females may affect the pharmacokinetics of ASDs.[179] Absorption can be influenced by nausea and vomiting of pregnancy. Both hepatic metabolism and renal function increase during pregnancy. The binding capacity of albumin is decreased during pregnancy, resulting in decreased protein binding for highly bound drugs. Unbound fractions of phenobarbital, phenytoin, and valproate increase with decreased concentrations of albumin.[204–206] For drugs predominately metabolized by the liver with a restrictive clearance (eg, carbamazepine and valproate), decreased protein binding without changes in intrinsic clearance should result in a decrease in total drug concentrations; unbound drug concentrations usually remain unchanged. For drugs with both increased hepatic metabolism and decreased protein binding (eg, phenytoin and phenobarbital), both

total and unbound plasma concentrations decrease, but not necessarily proportionately.

The clearance of lamotrigine increases as pregnancy progresses, presumably related to the impact of estrogen on lamotrigine metabolism.[207] This alteration in clearance changes immediately postpartum. Preliminary data suggest that oxcarbazepine concentrations may also decrease as pregnancy progresses.[208]

The effects of changes in renal function during pregnancy on ASD concentrations are not well known.[208] Renal blood flow and glomerular filtration rate increase during pregnancy. Thus, the renal clearance of drugs that are predominately excreted through the kidneys, such as gabapentin, levetiracetam, and pregabalin, may increase during pregnancy.

During pregnancy, serum levels of ASDs (including free serum levels for highly protein-bound drugs) can be monitored. In this case, a prepregnancy level would be optimal for comparison. Dosage adjustments may help to prevent the increase in seizure frequency that may occur in pregnant females with epilepsy.

For P.Z., it can be presumed that significant exposure of the fetus to any teratogenic influence of ASD has already occurred. Optimization of seizure control is now the primary concern for her. Any major alterations in P.Z.'s ASD regimen should be made cautiously to avoid precipitating seizures. P.Z. can also be referred to the antiepileptic drug (AED) pregnancy registry at Massachusetts General Hospital (1-888-233-2334 or www.aedpregnancyregistry.org). The registry collects data to provide safety recommendations for ASD use in pregnancy. The website also contains useful patient education on the subject.

VITAMIN K SUPPLEMENTATION

There is a theoretical risk that babies born to females with epilepsy who are taking an enzyme-inducing ASD are at risk of hemorrhage secondary to increased metabolism of vitamin K–dependent clotting factors. Based on available evidence, the AAN neither supports nor refutes the practice of supplementing vitamin K in females receiving

carbamazepine, phenobarbital, primidone, or phenytoin.[198] One could consider supplementing vitamin K 10 mg orally daily from 36 weeks of gestation until delivery.[209] Furthermore, all infants are recommended to receive IM vitamin K at birth to prevent hemorrhagic complications.[210]

BREAST-FEEDING

The risk of drug exposure to the breast-feeding infant should be weighed against the benefits of breast-feeding.[211] All drugs transfer into milk to some extent and several drug characteristics help predict how much will pass into the milk, including protein binding, milk/plasma (M/P), maternal plasma concentration, and so on. For the ASDs, a large intersubject variability in the M/P ratio exists, presumably owing to a difference in volume and composition of the milk. Thus, the M/P ratio is not useful for predicting infant ASD exposure. Reviews on ASD and breast-feeding are available.[212] For most first-generation ASDs (carbamazepine, phenytoin, valproic acid, and phenobarbital), breast-feeding results in negligible ASD plasma concentrations in the infants. For the newer ASDs, less data are available for breast-feeding should be done cautiously, and the infant should be monitored for excess ASD plasma concentrations and toxicity. Moreover, ASD and patient-specific factors should be extensively assessed and reviewed with the patient regarding the potential implications of breast-feeding while taking ASDs. P.Z. should be educated on the risks associated with drug transfer into the breast milk. Once she delivers, reevaluation and optimization of P.Z.'s ASD therapy should occur.

STATUS EPILEPTICUS

Characteristics and Pathophysiology

CASE 60-12

QUESTION 1: V.S., a 22-year-old, 187.40-pound (85-kg) male, was recently diagnosed as having idiopathic epilepsy with generalized tonic–clonic seizures. For the past 3 months, he has been treated with 600 mg/day of carbamazepine, which completely eliminated his seizures. His steady-state carbamazepine serum concentration was 10 µg/mL. While at his parents' home, he had two tonic–clonic seizures, each lasting 3 to 4 minutes. On arrival at the hospital (~30 minutes after the first seizure began), he was noted to be only semiconscious. His blood pressure was 197/104 mm Hg, his pulse was 124 beats/minute, respirations were 23 breaths/minute, and his body temperature was 100.4 °F (38 °C) rectally. Shortly after his arrival, another generalized tonic–clonic seizure began.

How does V.S.'s current condition meet accepted diagnostic criteria for SE? What risks are associated with SE?

SE is operationally defined as "either continuous seizures lasting at least 5 minutes or two or more discrete seizures between which there is incomplete recovery of consciousness."[213] Because V.S. has had three seizures within slightly more than 30 minutes and did not return to his baseline level of consciousness between seizures, his present condition meets this definition. V.S. is experiencing generalized convulsive SE; this is the most common type, and it is associated with the greatest risk of213systemic and neurologic damage. SE also may be characterized by nonconvulsive seizures that produce a persistent state of impaired consciousness, or by focal seizures (with or without impaired awareness). These forms of SE are associated with much lower morbidity and mortality than generalized convulsive SE.

Uncontrolled, convulsive SE can cause severe metabolic and hemodynamic alterations. V.S.'s vital signs (tachycardia, elevated blood pressure, increased respiratory rate, and elevated body temperature) are typical for a patient in SE. Prolonged, severe muscle contractions and CNS dysfunction from uncontrolled seizure discharges result in hyperthermia, cardiorespiratory collapse, myoglobinuria, renal failure, and neurologic damage. Even in the absence of convulsive muscle movements, neurologic damage can occur from excessive electrical activity and the resultant alterations in brain metabolism. When seizure activity persists longer than ~30

minutes, failure of mechanisms that regulate cerebral blood flow is more likely; this failure accompanies dramatic increases in brain metabolism and demand for glucose and oxygen. Failure to meet the metabolic demands of brain tissue results in accumulation of lactate and cell death. Peripherally, lactate accumulates, and serum glucose and electrolytes are altered. After 30 minutes of seizure activity, the body often fails to compensate for increased metabolic demands, and cardiovascular collapse can occur.[214,215] For these reasons, SE is considered a medical emergency that requires immediate treatment to prevent or lessen both systemic and neurologic damage. Mortality in adults with SE is ~20%[213]; fatal outcome is often the result of the condition that precipitated SE (eg, acute symptomatic causes, such as cardiopulmonary arrest, stroke). Long-term neurologic consequences of severe SE may include cognitive impairment, memory loss, and worsening of seizure disorders.

General Treatment Measures and Antiseizure Drug Therapy

Case 60-12, Question 2: What is a general treatment plan for V.S.'s episode of SE?

The immediate therapeutic concern in V.S. is to ensure ventilation, stabilize vital signs, and terminate current seizure activity. If possible, an airway should be placed for airway protection and if ventilatory support is needed; however, this may not be possible while he is convulsing. Objects (eg, spoons, tongue blades) should never be placed into the mouth of a patient during a seizure. If airway placement is impossible, V.S. should be positioned on his side to allow drainage of saliva and mucus from the mouth and prevent aspiration. An IV line should be established using normal saline, and blood should be obtained for serum chemistries (especially glucose and electrolytes), ASD serum concentrations, and toxicology screens. Glucose, 25 g (50 mL of 50% dextrose solution) by IV push

should be administered to correct any hypoglycemia, which may be responsible for SE.[216]

IV administration of rapid-acting anticonvulsant medication should begin as soon as possible to terminate V.S.'s seizure activity. SE becomes more resistant to treatment the longer the seizure continues; thus, treatment is more likely to stop seizures the sooner it is administered.[213] For in-hospital treatment of SE, IV medication administration is usually preferred.

Case 60-12, Question 3: Which anticonvulsants are available for IV administration? Evaluate the available drugs and recommend a drug, dosage, and regimen for initial treatment of SE in V.S.

Lorazepam, phenytoin, and fosphenytoin are the agents most commonly studied and as IV therapy in the initial treatment of SE.[213,217] Phenytoin and fosphenytoin are indicated for treatment of SE, but owing to limitations on their rates of infusion, the onset of their peak effect may be delayed. Therefore, phenytoin or fosphenytoin is usually used after initial treatment with lorazepam.

IV valproate sodium (Depacon®), phenytoin or fosphenytoin, and levetiracetam have been used. Refer to **Table 60-6** for more information regarding dosing and rate of administration. Lacosamide is also available in an IV formulation, and there are several case reports and some prospective trials of its successful use for refractory nonconvulsive SE.[218,219] IV phenobarbital is usually reserved for SE that does not respond to benzodiazepines and phenytoin.[213]

Table 60-6
Status Epilepticus Treatment

Stage	Agent and Dosing	Infusion Rate	Adverse Drug Effects/Clinical Pearls
Emergent[a]	■ Lorazepam 0.1 mg/kg (max 4 mg) IV ■ Midazolam 0.2 mg/kg (max 10 mg) IM ■ Diazepam 0.2 mg/kg PR	■ Lorazepam: 2 mg/minute	■ Chosen based on of access ■ Diazepam can be used at home by a trained family member, whereas both lorazepam and midazolam require administration by a medical professional ■ Differences in pharmacokinetics are addressed in Table 60-7
Urgent	■ Phenytoin/fosphenytoin 20 mg/kg IV ■ Levetiracetam 40–60 mg/kg IV ■ Valproate sodium 20–40 mg/kg IV	■ Phenytoin: 50 mg/minute (adults), 1 mg/kg/minute (children) ■ Fosphenytoin: 150 mg PE/minute (adults), 3 mg PE/kg/minute (children) ■ Levetiracetam: 2–5 mg/kg/minute ■ Valproate sodium: 3–6 mg/kg/minute (adults), 1.5–3 mg/kg/minute (children)	■ Fosphenytoin can be given via IM route and its IV administration rate is faster than phenytoin ■ Valproic acid might not be the best agent for patient with end-stage liver disease ■ Levetiracetam has the lowest drug interactions risk
Refractory	■ Midazolam 0.2 mg/kg IV load ■ Propofol 20 μg/kg/minute CIVI	■ Midazolam: 2 mg/minute (loading) then 0.05–2 mg/kg/hour CIVI ■ Propofol: may increase to 30–200 μg/kg/minute CIVI	■ Midazolam has an active metabolite, and its half-life can be prolonged especially in patients with renal impairment, whereas propofol has the risk to cause hypertriglyceridemia ■ Propofol at higher doses (>80 μg/kg/minute) is associated with PRIS, which is characterized by metabolic acidosis, rhabdomyolysis, and renal failure
Super-refractory	■ Pentobarbital 5–15 mg/kg load ■ Ketamine 1.5–4.5 mg/kg IV load	■ Pentobarbital: ≤50 mg/minute (load), then 0.5–5 mg/kg/hour CIVI ■ Ketamine: 0.5 mg/kg/minute (load), then 1.2–7.5 mg/kg/hour CIVI	■ Pentobarbital can cause ileus, cardiac suppression, and hypotension ■ Ketamine might trigger or worsen the condition of patients with psychiatric illness

CIVI, continuous IV infusion; IM, intramuscular; IV, intravenous; PE, phenytoin sodium equivalent; PR, per rectum; PRIS, propofol-related infusion syndrome.

[a]May repeat after 5–10 minutes and used as needed for seizures control.

Four IV regimens for generalized convulsive SE were directly compared in one randomized controlled trial.[220] The study evaluated diazepam followed by phenytoin, lorazepam alone, phenobarbital alone, and phenytoin alone. For initial IV treatment of overt generalized SE, lorazepam was more effective than phenytoin alone. Lorazepam was as effective as the other two regimens, and it was easier to use.

IV administration of either diazepam or lorazepam is usually effective for rapid termination of seizure activity in SE.[221] Owing to diazepam's higher lipid solubility, it redistributes from the CNS to peripheral tissues rapidly after administration; this results in a short duration of action (<60 minutes).[222] Lorazepam's lower lipid solubility

prevents rapid redistribution and accounts for its longer duration of action.[220] Lorazepam may be effective for up to 72 hours.[223,224] Owing to this longer duration, lorazepam is the preferred benzodiazepine for immediate treatment of SEs.[216,217]

Lorazepam 0.1 mg/kg (up to 4 mg/dose) given intravenously at 2 mg/minute would be appropriate initial therapy for V.S.[216,225] Lorazepam may cause significant venous irritation, and the manufacturer recommends dilution with an equal volume of normal saline solution or water for injection before IV administration. Lorazepam may be repeated after 5 minutes if seizures continue. The efficacy of lorazepam depends on rapid achievement of high serum and CNS concentrations. Although lorazepam can be administered IM, this route should not be used for treatment of SE because it is unlikely that it would achieve serum concentrations necessary for termination of seizure activity and there is little experience with its use for terminating SE. Midazolam given IM has been shown to quickly and effectively terminate SE when used in out-of-hospital settings. This treatment is an acceptable alternative for in-hospital use when IV access is not feasible.[226,227] The most common adverse effects after IV administration of benzodiazepines are sedation, hypotension, and respiratory arrest.[222] These adverse effects are usually short-lived and, when adequate facilities are available for assisted ventilation and administration of fluids, they usually can be managed without major risk to the patient. Respiratory depression occurs most commonly in patients who receive multiple IV medications for control of SE. Refer to **Table 60-7** for more pharmacokinetic comparisons of benzodiazepines.[228–233]

Table 60-7
Pharmacokinetic Properties of Benzodiazepines Used for Seizures

Agent	Onset (minutes)	Duration of Action	Vd (L/kg)	Metabolism	Excretion	$T_{1/2}$ (hours)
Lorazepam IV	1.6	4–6 hours	1.3	Liver to inactive metabolites	Hepatic metabolism to inactive metabolites; IV formulation with propylene glycol	12
Midazolam IM	3.3	2–6 hours	1–3	CYP3A4 to active metabolite	Renally cleared	3–5
Midazolam IN	3–10	—				2–6
Midazolam IV	1.5–2.5	30–80 minutes				3–4
Diazepam IV	1–3	15–30 minutes	0.8–1	CYP2C19 and CYP3A4 to active metabolites	Renally cleared; IV formulation with propylene glycol	48, but removed from plasma quickly and therefore short duration of action
Diazepam PR	5–10	15–30 minutes				

CYP, cytochrome P-450; IM, intramuscular; IN, intranasal; IV, intravenous; PR, per rectum.

INTRAVENOUS PHENYTOIN AND FOSPHENYTOIN

Case 60-12, Question 4: V.S. was given lorazepam 4 mg IV. Seizure activity ceased 2 minutes after the injection was completed. What drug should be administered to V.S. for prolonged control of seizures? What is the recommended dose, route, and method of administration?

Continued effective seizure control is important for patients who experience SE. After a benzodiazepine is administered for emergent therapy, an urgent control therapy agent is typically administered. The drug of choice for urgent therapy has not been established, but options include phenytoin/fosphenytoin, valproate sodium, or levetiracetam.[225] Currently, some ASD agents, such as levetiracetam and lacosamide, are being administered as an intravenous bolus over 5–10 minutes to control seizures.[234–237] Levetiracetam at doses of 2000–4500 mg showed to be safe and tolerable when administered undiluted and rapidly through the intravenous route. Other studies also showed that rapid infusion of levetiracetam has comparable efficacy to phenytoin and valproic acid when used to treat SE.[238,239]

The Established Status Epilepticus Treatment Trial (ESETT) was a double-blind, randomized controlled trial of 384 children and adults with convulsive SE that was unresponsive to an adequate dose of a benzodiazepine.[238] Patients were randomized to fosphenytoin 20 mg/kg (maximum dose: 1500 mg), levetiracetam 60 mg/kg

(maximum dose: 4500 mg), or valproate sodium 40 mg/kg (maximum dose: 3000 mg) administered IV over 10 minutes. There was no difference in the primary outcome of absence of clinically relevant seizures and improvement of consciousness at 60 minutes (45% with fosphenytoin, 47% with levetiracetam, and 46% with valproate) or any of the secondary outcomes including admission to intensive care unit, time to termination of seizure, hypotension, intubation, or death. There are many limitations to the interpretation of this trial including unconventional dosing for both phenytoin and levetiracetam and a median duration of seizure at enrollment of more than an hour. Overall, fosphenytoin, levetiracetam, and valproate sodium remain options for urgent control of SE and choice of drug should be individualized.[238]

The availability of fosphenytoin for IV administration has provided an additional option for administration of phenytoin in the treatment of SE, and in most centers, fosphenytoin is preferred over phenytoin. Use of this phenytoin prodrug allows more rapid administration of large IV loading doses of phenytoin with less risk of injection site complications. Fosphenytoin is also better tolerated than phenytoin.[227] Fosphenytoin itself is inactive; the therapeutic effect results from its conversion to phenytoin.[103,104]

In the United States, phenytoin is considered the long-acting anticonvulsant of choice for most patients with generalized convulsive SE.[217] Phenytoin causes much less sedation and respiratory depression than drugs such as phenobarbital when it is used in conjunction with IV benzodiazepines.[216] V.S.'s maintenance carbamazepine therapy was previously effective. Without obvious precipitating factors such as head trauma, CNS infection, and drug or alcohol abuse, SE, in a patient with a history of epilepsy, most commonly results from poor adherence with maintenance ASD medication. Therefore, IV fosphenytoin (the prodrug of phenytoin that has less adverse effects) is a good choice for re-establishing effective ASD therapy for V.S. Phenytoin is an acceptable alternative if fosphenytoin is unavailable.

Loading dose

Whether or not V.S. has a detectable serum concentration of carbamazepine, he should be given an IV loading dose of either fosphenytoin (20 mg/kg PE IV at 150 mg/minute) or phenytoin (20 mg/kg IV at 50 mg/minute). After administration of either of these loading doses, serum phenytoin concentrations should remain >10 µg/mL for ~24 hours; this will allow time for determination of V.S.'s serum carbamazepine concentration and estimation of an appropriate maintenance dose of oral carbamazepine once oral therapy can be restarted. In this setting, the use of IV phenytoin or fosphenytoin is a temporary measure. V.S.'s previous positive response to carbamazepine indicates that he should likely continue to receive this drug as his oral maintenance medication.

IV phenytoin can be administered by direct injection into a running IV line of normal saline but is incompatible with dextrose solutions. The rate of administration should be no faster than 50 mg/minute to minimize the risk of hypotension and acute cardiac arrhythmias. Cardiovascular status (blood pressure, electrocardiogram) should be monitored closely during administration. Hypotension or electrocardiographic abnormalities usually reverse if the administration of phenytoin is slowed or stopped temporarily. Fosphenytoin can be given by either direct IV injection or, after dilution in any suitable IV solution, by infusion at up to 150 mg PE/minute.[103] Absence of propylene glycol as a diluent renders fosphenytoin potentially less likely than phenytoin to cause cardiovascular adverse effects, but this advantage is not well supported.[240] Electrocardiographic and blood pressure monitoring is recommended when this drug is given IV. Pruritus and paresthesia, usually localized to the face and groin, are relatively common adverse effects during IV fosphenytoin administration. These sensations are not allergic reactions to the medication. Their occurrence is related to the administration rate, and they are reversible with temporary discontinuation or slowing of the injection.[103]

Maintenance Therapy

The undetectable serum carbamazepine concentration appears to confirm the role of nonadherence in this episode of SE. Because V.S. was previously well controlled on 600 mg/day, this would be a reasonable target dose. Because V.S. may not tolerate carbamazepine if restarted at the prior maintenance dose, gradually escalating up to this dose should be initiated as soon as V.S. can take oral medication. V.S. should be counseled regarding the importance of taking his medication according to directions, and any potential barriers to adherence should be addressed.

Phenobarbital may be useful for treatment of SE if the patient cannot tolerate phenytoin or when seizures continue after administration of appropriate loading doses of phenytoin. Patients who receive phenobarbital after being treated with IV benzodiazepines should be monitored closely for respiratory depression because this effect may be additive. Equipment and personnel to provide ventilatory assistance should be available.[216]

Alternative Therapies for Refractory Status Epilepticus

SE that does not respond to lorazepam and a longer-acting agent (eg, phenytoin/fosphenytoin, valproate, levetiracetam, phenobarbital, or lacosamide) is considered *refractory status epilepticus (RSE)*. Between 20% to 40% of patients with SE will progress to RSE. In such circumstances, an alternative long-acting agent from those mentioned above may be considered; and, in recent years, the use of such “third-line” agents was a common practice. Recently, it has become a more common practice to escalate therapy to the use of an anesthetic agent after the failure of second-line therapy.[217] The most commonly used anesthetic agents for RSE are midazolam and propofol; pentobarbital is also sometimes used. Significant respiratory depression is expected with these therapies; patients require intubation and mechanical ventilation. In addition,

vasopressors, such as norepinephrine, may be required to control hypotension.[241] Continuous EEG monitoring also is required to assess the anticonvulsant effect of the drug and to gauge the level of anesthesia.

Midazolam is given as a loading dose of 0.2 mg/kg IV and is followed by an IV infusion of 0.2 to 2 mg/kg/hour.[216] Many practitioners adjust the infusion rate to control electrographic seizures and/or to produce a burst-suppression EEG pattern.[242] Most protocols for anesthetic therapy of RSE recommend attempts at gradually reducing the dose of medication after 24 hours of treatment. If clinical or EEG seizure activity recurs, the dose is increased again to produce the desired EEG pattern. Patients receiving midazolam may experience tachyphylaxis and require higher doses with longer durations of treatment. Anesthetic agents may need to be continued for several days or even weeks in some patients.

Continuous IV infusions of propofol are useful for RSE, but patients should be monitored for propofol-related infusion syndrome (PRIS), which can occur with high doses.[241]

Other treatment strategies might be considered in case of super-RSE when a drug-induced coma approach fails. Ketamine is another option for RSE that has a growing interest; however, there is limited data to support its use.[243] One theory about pathophysiology of RSE is that gamma-aminobutyric acid (GABA) receptors are internalized and *N*-methyl-D-aspartate (NMDA) receptors upregulate in this state. As an NMDA antagonist, ketamine may be an option for RSE. Recommended dosing is 1 to 4 mg IV load, then 1 to 5 mg/kg/hour as an IV infusion. Ketamine does not cause hypotension but may cause emergence psychosis/hallucinations and increased salivation.

Limited evidence is available for the use of inhaled anesthetics, lidocaine infusion, electroconvulsive therapy, ketogenic diet, or surgical intervention in super-RSE.[225,244]

Acute Ischemic and Hemorrhagic Stroke

Oussayma Moukhachen and Philip Grgurich

CORE PRINCIPLES		CHAPTER CASES
1	Acute ischemic and hemorrhagic stroke are medical emergencies, requiring prompt medical attention at the first sign of symptoms. Signs and symptoms of cerebrovascular disease usually occur acutely and vary depending on the area of the brain involved. Ischemic and hemorrhagic events have similar symptoms and must be distinguished before initiating treatment.	**Case 61-1 (Question 1–3), Table 61-2**
2	Acute goals of therapy for ischemic stroke focus on early reperfusion strategies to salvage brain tissue and restoring blood flow, in addition to prevention of complications such as	**Case 61-1 (Question 4)** **Case 61-2 (Question 7),** **Figure 61-2, Table 61-2**

	venous thromboembolism, aspiration pneumonia, and hemorrhagic conversion of the ischemic stroke. The sequelae of stroke on functional status and the degree of disability are assessed using scales such as the modified Rankin Scale (mRS).	
3	Treatment of acute ischemic stroke includes the use of alteplase given via intravenous (IV) infusion. Alteplase should be started after confirming an event is ischemic and not hemorrhagic. The treatment window for use of alteplase is limited to 4.5 hours after the onset of neurologic symptoms. Indication and contraindication criteria for administration of IV alteplase must be followed to reduce the risk of intracranial hemorrhage.	**Case 61-2 (Question 1), Table 61-3**
4	Provision of appropriate reperfusion strategy (IV alteplase or endovascular thrombectomy or both), supportive care during the hospitalization, and patient rehabilitation are key to improve patient prognosis.	**Case 61-2 (Questions 2, 3, 5, 6, 8), Figure 61-1**
5	Blood pressure control before, during, and after administration of IV thrombolytics and endovascular thrombectomy is extremely important to reduce the risk of intracranial hemorrhage.	**Case 61-2 (Question 4), Table 61-4**
6	Within 14 days of an ischemic event, the	**Case 61-2 (Question 5, 7), Tables 61-5, 61-6**

	risk of recurrence of a stroke is the highest. Acutely, antiplatelet therapy is typically initiated 24 hours after IV thrombolysis. In patients who did not receive IV thrombolysis, dual antiplatelets for 21 days are currently recommended.	
7	Secondary lifelong prevention of a non-cardioembolic ischemic stroke and transient ischemic attacks involves the use of antiplatelet agents as well as controlling modifiable risk factors. Anticoagulants are indicated in high-risk patients with atrial fibrillation. Surgical interventions such as carotid endarterectomy or carotid artery angioplasty/stenting may be appropriate in select patients. Selection of a specific approach is dependent on patient comorbidities.	**Case 61-2 (Question 9), Tables 61-1, 61-5**
8	The strongest risk factor for hemorrhagic stroke because of nontraumatic intracerebral hemorrhage is uncontrolled hypertension. Intracerebral hemorrhage may also occur as a result of an anatomic abnormality in the brain or a disease process, such as a brain tumor. Bleeding disorders, including those induced by anticoagulant drugs, also predispose patients to intracerebral hemorrhage.	**Case 61-3 (Question 1)**
9	Acute treatment of intracerebral	**Case 61-3 (Question**

	hemorrhage focuses on minimizing hemorrhage expansion through careful blood pressure control and reversal of coagulopathies, when appropriate, as well as prevention and management of elevated intracranial pressure.	**2–6)**
10	Modifiable risk factors for hemorrhagic strokes include blood pressure control, smoking cessation, and avoiding excessive alcohol and cocaine use.	**Case 61-3 (Question 7)**
11	Rehabilitation after a cerebrovascular event is essential to patient recovery. Common complications encountered in rehabilitation include spasticity, depression, and neurogenic bowel or bladder. Pharmacotherapy interventions should be directed at each of these complications, with the goal of improving the patient's quality of life and ability to function independently.	**Case 61-4 (Question 1)**

INTRODUCTION

Acute ischemic stroke (AIS), transient ischemic attack (TIA), and hemorrhagic stroke result from either inadequate blood flow to the brain (ie, cerebral ischemia) with subsequent infarction of the involved portion of the central nervous system (CNS) or hemorrhages into the parenchyma or surrounding structures of the CNS and subsequent neurologic dysfunction. This group of cerebrovascular disorders is the fifth leading cause of deaths among adults in the United States.[1] Ischemic strokes constitute 87% of all

cases of cerebrovascular disorders, whereas hemorrhagic strokes account for 13%.

Transient Ischemic Attack

A transient ischemic attack (TIA) is defined as a transient episode of neurologic dysfunction caused by focal brain, spinal cord, or retinal ischemia not associated with permanent cerebral infarction.[2] It used to be described as the clinical condition in which a patient experiences a temporary (lasting <24 hours) focal neurologic deficit such as slurred speech, aphasia, weakness or paralysis of a limb, or blindness. However, the original description is no longer valid because it implied that TIAs are minor and that symptoms disappeared completely, whereas recent studies and imaging techniques have shown that TIA can actually lead to brain injury and increased risk of recurrent stroke. Some would argue that the TIA term should not be even used at all.

Acute Ischemic Stroke

Acute ischemic stroke (AIS) is defined as an infarction of the CNS. Unlike TIAs, an AIS may be either symptomatic or silent.[2] Clinical signs of focal or global cerebral, spinal, or retinal dysfunction caused by a CNS infarction are the manifestation of symptomatic AIS. The infarct can affect either the anterior or posterior cerebral circulation, or both. An AIS is categorized into five subtypes depending on the cause as described by the multicenter Trial of Org 10172 in Acute Stroke Treatment (TOAST) investigators.[3] According to the TOAST classification, the five subtypes of AIS include (a) large artery atherosclerosis or large-vessel occlusion (LVO), (b) small artery atherosclerosis (also referred to as lacunar), (c) cardioembolic, (d) undetermined causes, and (e) strokes of other causes.

Intracranial Hemorrhage

Intracranial hemorrhage (ICH) involves the movement of blood from blood vessels inside the brain into the brain tissue, or parenchyma, or its surrounding structures. Clinical symptoms associated with ICH are similar to, but often more severe than, those resulting from ischemic strokes. These symptoms commonly include neurologic deficits as well as headache, vomiting, and a decreased level of consciousness. Some patients may experience other symptoms including seizures, electrocardiographic (ECG) abnormalities, and a stiff neck. Depending on the type and size of the ICH, symptoms may develop abruptly or worsen slowly over minutes to hours.

The location of the hemorrhage within the intracranial vault determines the type of ICH. ICHs occur when blood moves into the brain parenchyma, whereas other types of hemorrhages develop when blood moves into spaces around the brain tissue.

EPIDEMIOLOGY

An estimated 7 million Americans age 20 years or older reported having a stroke.[1] Each year, an estimated 795,000 individuals in the United States experience a new or recurrent stroke and ~610,000 of these are first attacks.[1] There is a higher regional incidence and prevalence of stroke and a higher stroke mortality rate in the southern part of the United States compared to the rest of the country. Younger males have a higher incidence of stroke than do females in the same age group; however, in the age group older than 75 years, females have a higher incidence. Blacks and Hispanics have an increased risk of stroke compared with Whites. The precise reasons for these differences are unclear, but genetic, geographic, dietary, and cultural factors have been considered.[1,4] In addition, the incidence of risk factors for stroke such as hypertension, diabetes, and hypercholesterolemia differs among racial groups. There is a strong relationship between the occurrence of TIA and an increased risk of subsequent cerebral infarction.[1,2] The risk of an ischemic stroke is highest in the first 30 days after a TIA, and the risk within 90

days of a TIA is 3% to 17.3%. In addition, nearly 25% of patients who experience a TIA will die within a year.[2] Risk factors for AIS/TIA are listed in **Table 61-1** and are categorized as either nonmodifiable (eg, age, race, gender) or modifiable (eg, hypertension, high cholesterol level, smoking).[5] Prevention efforts for AIS/TIA will be focused on elimination and control of the modifiable risk factors.[5,6]

Table 61-1
Risk Factors for Transient Ischemic Attack and Acute Ischemic Stroke

Modifiable	Potentially Modifiable	Nonmodifiable
Cardiovascular disease (coronary heart disease, heart failure, peripheral arterial disease) Hypertension Cigarette smoking Diabetes Asymptomatic carotid stenosis Atrial fibrillation Sickle cell disease	Metabolic syndrome Alcohol abuse (≥5 drinks daily) Hyperhomocysteinemia Drug abuse (eg, cocaine, amphetamine, methamphetamine) Hypercoagulability (eg, anticardiolipin, factor V Leiden, protein C deficiency, protein S deficiency, antithrombin III deficiency)	Age (doubling every 10 years after age 55) Race (Blacks > Hispanics > Whites) Biologic sex (males > females) Low birth weight (<2500 g) Family history of stroke (paternal > maternal)
Dyslipidemia (high total cholesterol, low HDL)	Oral contraceptive use (females 25–44 years old)	
Dietary factors (sodium intake <2300 mg/day; potassium intake <4700 mg/day)	Inflammatory processes (eg, periodontal disease, cytomegalovirus, *Helicobacter pylori* seropositive)	
Obesity Physical inactivity	Acute infection (eg, respiratory infection, urinary tract infection)	
Postmenopausal hormone therapy (females 50–74 years old)	CD40 ligand >3.71 ng/mL in females free of cardiovascular disease	

	IL-18 upper tertile	
	hs-CRP >3 mg/L in females ages 45 years and older	
	Migraine headaches	
	High Lp(a)	
	High Lp-PLA_2	
	Sleep-disordered breathing	

HDL, high-density lipoprotein; hs-CRP, high-sensitivity C-reactive protein; IL, interleukin; Lp(a), lipoprotein(a); Lp-PLA_2, lipoprotein-associated phospholipase A_2.

Source: Meschia JF, Bushnell C, Boden-Albala B, et al. Guidelines for the primary prevention of stroke: a statement for healthcare professionals from the American Heart Association/American Stroke Association. *Stroke*. 2014;45(12):3754–3832.

ICHs account for 10% of all strokes in North America, whereas subarachnoid hemorrhage, most commonly resulting from cerebral artery aneurysms, comprises 3% of all strokes. Hypertensive hemorrhage is the most common cause of ICH, with 46% of ICHs resulting from hypertension. A number of medications including warfarin and direct oral anticoagulants (DOACs), such as dabigatran, rivaroxaban, apixaban, and edoxaban, significantly predispose patients to ICH.

PATHOPHYSIOLOGY

Acute Ischemic Stroke

The neurologic sequelae of cerebral ischemia or infarction directly result from an embolic or thrombotic source. A clot may form in the heart, along the wall of a major blood vessel (eg, aorta, carotid, or basilar artery), or in small arteries penetrating deep into the brain. If the clot is located near the infarction, it is a *thrombus*; however, when the clot has migrated to the brain from a distant source, it is an *embolus*. Either can diminish or block blood flow to the affected area

of the brain. Disorders such as atrial fibrillation, mitral or aortic valve disease, patent foramen ovale, or coagulopathies are associated with the formation of clots that may embolize the brain. Inflammatory mechanisms also contribute to the development of ischemia, especially thrombotic lesions. Inflammation is thought to enhance the development of thrombotic lesions and result in sudden, intermittent occlusion of blood vessels. Disorders such as arteritis (Takayasu, giant cell), and Moyamoya syndrome are examples of diseases in which inflammation plays an important role in the development of brain ischemia.

Cerebral blood flow (CBF) in the normal adult brain is 30 to 70 mL/100 g of brain tissue per minute. When a thrombotic or embolic clot partially occludes a cerebral artery, causing a reduction in blood flow to <20 mL/100 g/minute, various compensatory mechanisms are activated. These include vasodilation and increased oxygen extraction. If the artery is further occluded and CBF is reduced to <12 mL/100 g/minute, the affected neurons become sufficiently anoxic to die within minutes.[7] Rapid reestablishment of blood flow to the ischemic area can delay, prevent, or limit the onset of infarction, improving the outcome of AIS.

Ischemia in the brain usually involves a core or focal region of profound ischemia that results in neuronal death. The extent of this region is dependent on the amount of brain that is perfused directly by the blood vessel that becomes occluded. There is a surrounding area of the brain that becomes marginally ischemic, with normal function being disrupted. This region of marginal ischemia is frequently called the *ischemic penumbra.* If ischemia continues, neurons in this region will die too. However, if normal blood flow is restored quickly, neurons in this area will survive. The *ischemic penumbra* is the targeted area for salvaging with our current available pharmacologic tools and endovascular interventions.[8]

Intracranial Hemorrhage

ICHs occur because of weakened intracranial blood vessels, elevated pressure inside the blood vessels, and anatomic abnormalities. Specific causes include hypertension, cerebral amyloid angiopathy, brain tumors, coagulopathies, and trauma. An anatomic derangement called arteriovenous malformations (AVMs) may also result in an ICH. An AVM is a clump of arteries and veins that are intertwined, resulting in weakened blood vessel walls. Pathophysiologic mechanisms differ depending on whether the bleeding occurs within the intracerebral space or outside the brain parenchyma in the subarachnoid, epidural, or subdural space.

Spontaneous ICH because of hypertension develops in areas of the brain where smaller blood vessels branch out from large blood vessels often at 90° angles, exposing the smaller vessels to the higher pressure of the preceding blood vessel and eventually resulting in bleeding of the smaller vessels.[9] In ICH, the movement of blood from blood vessels into the brain parenchyma causes local irritation of the brain tissue and edema. In the case of large hemorrhages and significant edema, mass effect can ultimately increase intracranial pressure (ICP), reducing blood flow to the brain and potentially causing brain tissue herniation.[10] Secondary brain injury occurs in many patients after spontaneous ICH. It is caused by a disrupted blood–brain barrier, release of inflammatory mediators, and progressive edema that may last 7 to 12 days.[11–14] In spontaneous ICH, hematoma enlargement is associated with poor outcomes. Nonmodifiable risk factors for hematoma expansion are large hematoma size and contrast extravasation on computed tomography (CT) at the time of presentation, whereas potentially modifiable risk factors include coagulopathies and ongoing uncontrolled hypertension after hospital admission.[15,16]

In subarachnoid hemorrhage, blood moves quickly into the cerebrospinal fluid (CSF), causing an acute elevation of ICP. Intracranial pressure refers to the pressure inside the intracranial vault and may be elevated because of brain tissue swelling, the development of a hematoma (collection of blood) inside the brain, or other conditions. Blood may also migrate into the intraventricular space or into the brain tissue.[17,18] Obstruction of CSF fluid

reabsorption and movement out of the brain because of the presence of blood in the brain can result in hydrocephalus, which is the buildup of CSF within the ventricles of the brain. Delayed cerebral ischemia, commonly referred to as *vasospasm* of the cerebral vasculature, may also complicate subarachnoid hemorrhage.

Epidural and subdural hematomas are other types of ICHs that occur outside the brain parenchyma. Depending on their size, epidural and subdural hematomas may significantly compress and displace brain tissue, resulting in elevated ICP and brain herniation because of mass effect. Brain herniation refers to abnormal movement of brain tissue across structures inside the skull that occurs because of elevated pressures within the intracranial vault. This squeezing of brain tissue can significantly compress CBF, consequently compromising oxygen delivery to the brain and causing brain cells to die.

CLINICAL PRESENTATION

Signs and Symptoms

Stroke and TIA can occur in the community or in the hospital. Clinical signs and symptoms of AIS and TIA must be recognized early by bystanders and/or providers to facilitate activation of stroke-specific management, the outcomes of which are time dependent. Early recognition of symptoms of AIS using the acronym BEFAST can facilitate a faster stroke chain of survival activation and provision of timely interventions.[19] The BEFAST acronym stands for *B* for balance, with the patient reporting of acute sudden loss of *b*alance or coordination; *E* for eyes, and the patient reporting blurred or unclear vision and gaze preference; *F* for *f*acial weakness or facial symmetry referred to as droop; *A* for *a*rm weakness and/or leg weakness; and, finally, *S* for *s*peech difficulty or slurring of. Given that time is important, *T* is for reminding to activate stroke system and alert.

Activation of the 9-1-1 system by patients or bystanders is recommended if stroke is suspected.

A sudden altered mental status or inability to move a limb in a hospitalized patient is also a potential sign of stroke that warrants further investigation.

Nausea and severe headache are often the most common cause of hemorrhagic stroke.

Stroke symptom severity can be rated using preferably the National Institutes of Health Stroke Scale (NIHSS).[8] The scale is available in table format online or in the current stroke guidelines. The link to the online scale can be found with this chapter's key websites. Pharmacists participating in the care of patients with stroke could complete the assessment of the stroke severity using the NIHSS as part of planning with the team to develop a pharmacist patient care process (PPCP).

Neuroimaging

The etiology of a stroke (ischemic vs hemorrhagic) is difficult to discern based solely on a physical and neurologic examination. As a result, CT or magnetic resonance imaging (MRI) is valuable in the evaluation of these patients. A noncontrast head CT is sensitive enough to assist in excluding hemorrhagic stroke and can be performed fairly rapidly in most hospitals. It is important to obtain the noncontrast head CT and its results within 20 minutes of the imaging, according to the current guidelines.[8] Computed tomography angiography (CTA) can be also added, and that would help in discerning the presence of large-vessel atherosclerosis or LVO, and stroke etiology.[20] Computed tomography-perfusion (CT-P) is also available in some institutions and can be used to quantify the ischemic core and to estimate the *ischemic penumbra*. This information can be helpful to guide the management. MRI is superior to a head CT with its tissue contrast, ability to obtain images in multiple planes, absence of artifacts caused by bone, vascular imaging capabilities, absence of ionizing radiation, and safer contrast

media. MRI also allows for a magnetic resonance angiogram to be performed, allowing visualization of the cerebrovasculature and possible identification of the precise location of the thrombus or embolus. MRI with diffusion-weighted imaging (DWI) will reveal an evolving infarct within minutes of stroke onset.

Unfortunately, MRI imaging is more difficult to perform in unstable patients, not always available in smaller hospitals or communities, and is unsafe to do in patients who have metallic implants, or pacemakers.

Obtaining more advanced imaging with CTA, CT-P, or even an MRI should not be favored over delaying therapy.[8]

GENERAL TREATMENT PRINCIPLES

Rapid recognition of stroke symptoms and immediate initiation of treatment are essential to the management of AIS or hemorrhagic stroke (**Fig. 61-1**). Appropriate pharmacotherapy of stroke requires a precise diagnosis.[8,21] It is vital to differentiate between an AIS/TIA and a hemorrhagic stroke because an inaccurate diagnosis can lead to the use of drugs that may cause severe morbidity or mortality. Interventions to prevent and treat AIS are directed at reducing risk factors, eliminating or modifying the underlying pathologic process, and reducing secondary brain damage. In hemorrhagic stroke, the emphasis of treatment is on preventing hematoma expansion, managing ICP, and providing supportive therapy to maximize neurologic function and minimize complications. Rehabilitation is a key component of long-term care for many patients, regardless of whether the stroke is ischemic or hemorrhagic.

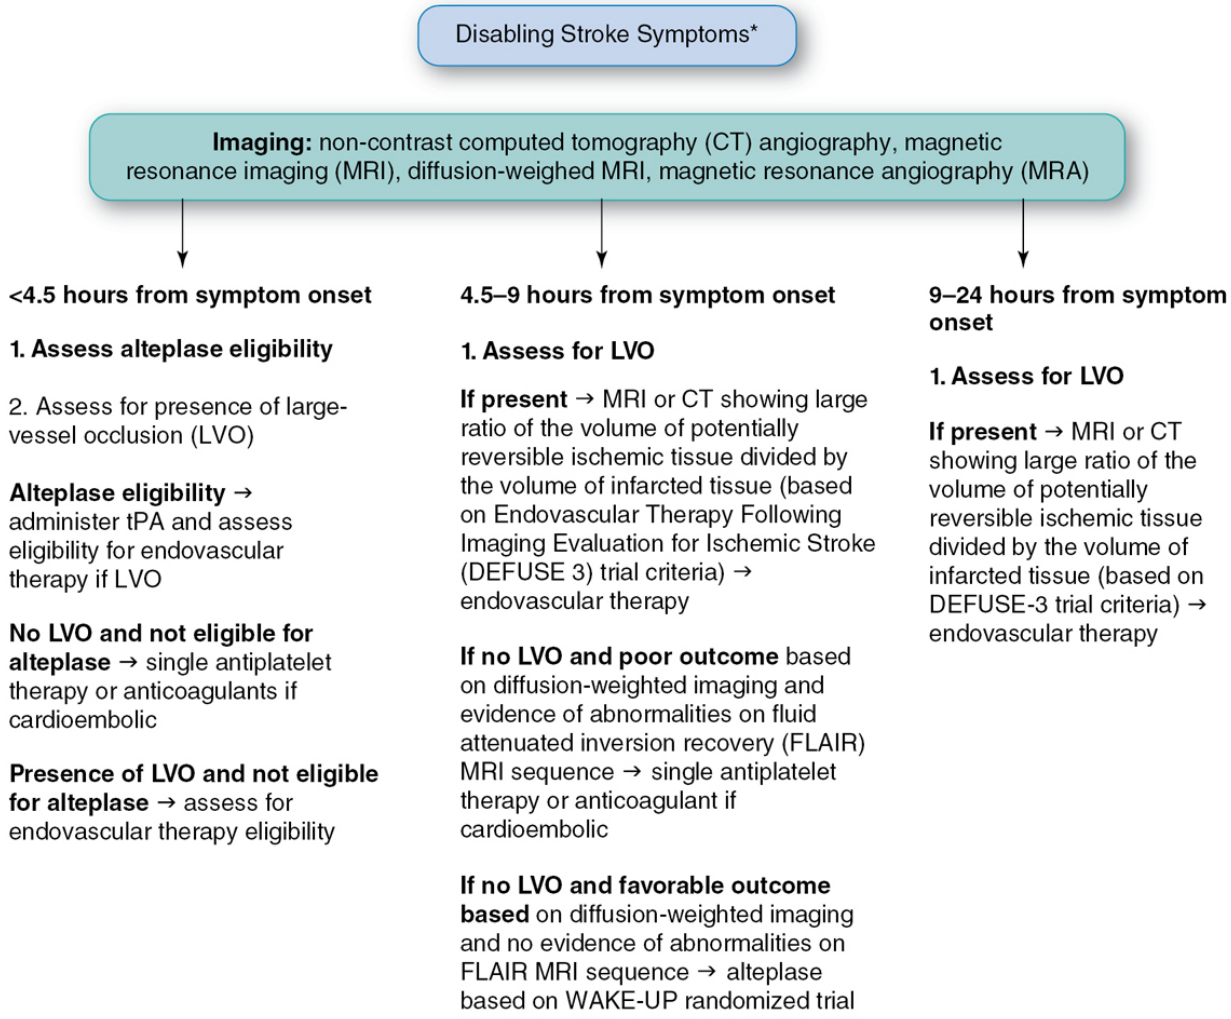

Figure 61-1 Treatment algorithm of acute ischemic stroke. (Adapted from Mendelson SJ, Prabhakaran S. Diagnosis and management of transient ischemic attack and acute ischemic stroke: a review. *JAMA*. 2021;325(11):1088–1098. doi:10.1001/jama.2020.26867.)

Any plan for *primary prevention* (ie, prevention of a first event) of TIA or AIS must address the control or reduction of risk factors (Table 61-1). The reader is referred to a detailed discussion of treatment of diseases[21] such as hypertension, diabetes, coronary artery disease, chronic kidney disease, and so on in their respective chapters (see Chapters 9, Essential Hypertension, 13, Acute

Coronary Syndrome, 28, Chronic Kidney Disease, and 53, Diabetes Mellitus).

ACUTE ISCHEMIC STROKE AND TRANSIENT ISCHEMIC ATTACK

Early Management of Acute Ischemic Stroke

CASE 61-1

QUESTION 1: P.C., a 65-year-old male (220.46 pounds [100 kg], 69 inches [175.26 cm]), is admitted through the emergency department (ED) with right-sided weakness. As per report, the patient was last seen well around 8:30 PM by his wife. Around 9:15 PM, P.C.'s son heard a bump and went upstairs to find his father on the floor. The patient had a slurred speech and had a right facial droop. At this point, 911 was called, and emergency medical services (EMS) picked up the patient and arrived at 9:45 PM at the ED of a large medical center certified for stroke. P.C. regained consciousness by the time he arrived in the ED. Both right extremities are flaccid. He is unable to speak but is capable of understanding instructions (ie, expressive aphasia). Gross ophthalmologic examination indicates right-sided neglect (inability of his eyes to track to the right or acknowledge the right side of his body). His blood pressure (BP) is 165/95 mm Hg and other vital signs are normal. Laboratory studies are all within normal limits. NIHSS score is 6.

Which signs and symptoms are consistent with AIS?

P.C. is showing typical signs of slurred speech, right facial droop, right-sided weakness and paralysis, loss of ability to speak, and right-sided neglect. His NIHSS score is 6, which categorizes his presentation as mild to moderately severe requiring acute inpatient hospitalization and rehabilitation.[22] The definition of severity of AIS according to the NIHSS score include normal severity for NIHSS score of 0 or 1; mild for a score of 1 to 4; mild to moderately severe for a score of 15 to 25, and very severe for an NIHSS score exceeding 25.

Case 61-1, Question 2: What interventions should have been initiated before arrival in the ED?

Immediate recognition of, and response to, stroke symptoms are essential to an optimal outcome. As soon as stroke symptoms are recognized, the emergency medical system should be activated. Emergency medical personnel should be trained to gather important historical information, especially when the symptoms started. This is defined as "when the patient was at their previous baseline or symptom-free state. For patients unable to provide information or who was awakened with stroke symptoms, the time of onset is defined as when the patient was last awake and symptom-free or known to be normal."[8] Use of a standardized evaluation tool such as the Cincinnati Prehospital Stroke Scale or the Los Angeles Prehospital Stroke Screen is useful in distinguishing stroke symptoms from other disorders, such as conversion disorder, hypertensive encephalopathy, hypoglycemia, complicated migraine, or seizures.[8,23]

General supportive care for respiratory and cardiovascular function should be initiated before transporting the patient to the ED. Mobile stroke units (MSUs) equipped with CT scanners and telemedicine links have shown an optimization of timely stroke treatments as opposed to regular ambulances and reinforcing the need for effective structured stroke approaches.[24] Although MSUs may not be available in all areas, professional societies and current guidelines encourage the development of stroke workflows to effectively manage patients with AIS by having a well-designed evaluation and treatment algorithm that addresses assessment and care of the patient from initial onset of symptoms through rehabilitation.[8] Patients with suspected cerebral infarction should be transported, if possible, to the closest certified primary stroke center. A certified primary stroke center would have a multidisciplinary team that would be activated and notified by the emergency personnel while a potential patient with stroke is en route.[23] If a primary stroke center is not locally available, patients can be stabilized in an acute

stroke–ready hospital. In these situations, local providers may use practice arrangements such as telemedicine with comprehensive stroke centers, which allows the provision of advanced care under the supervision of experts at a comprehensive stroke center. The organization of stroke centers and their capacity to provide care can be found in **Figure 61-2**.

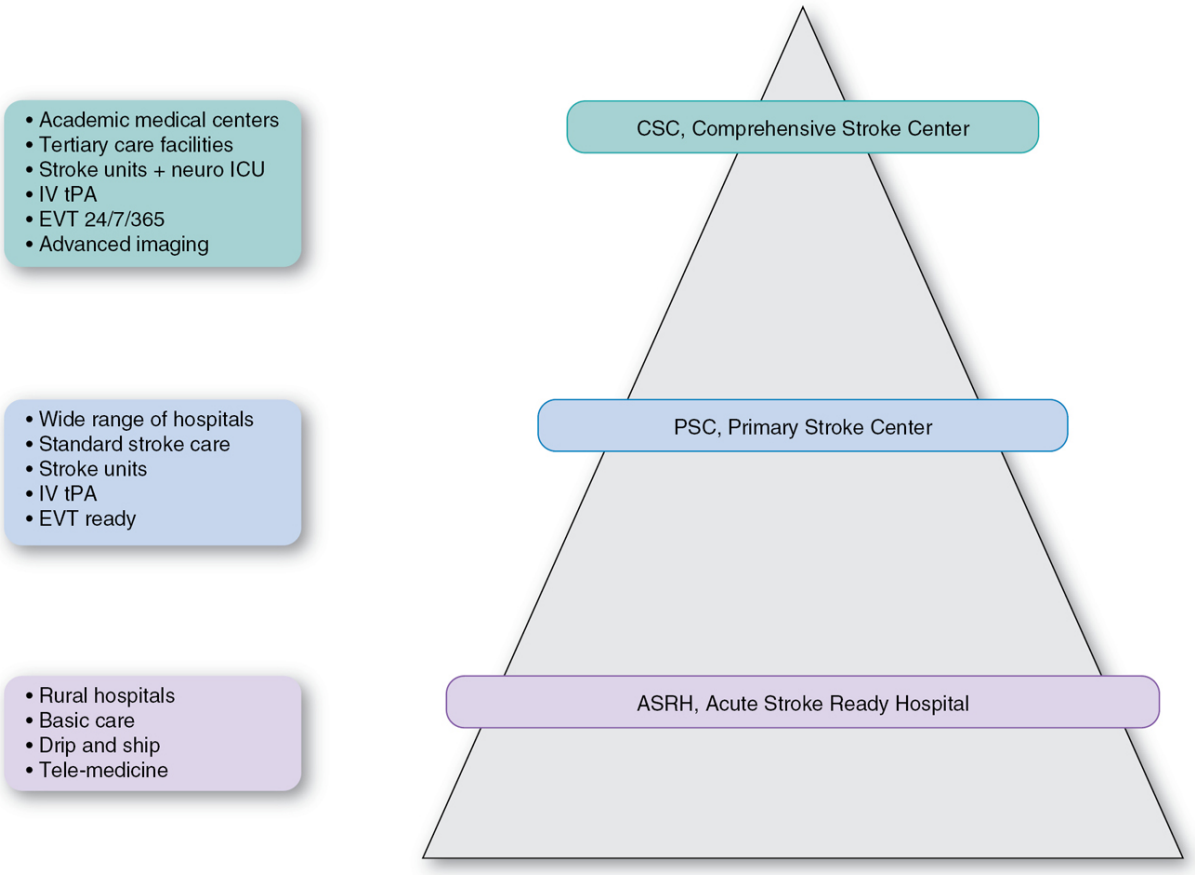

Figure 61-2 Organizations of Stroke Centers and capacity to provide acute stroke care. EVT, endovascular therapy; ICU, intensive care unit; IV tPA, intravenous tissue plasminogen, alteplase. (Source: Reprinted with permission from Herpich F, Rincon F. Management of acute ischemic stroke. *Crit Care Med*. 2020;48(11):1654–1663.)

CASE 61-1, QUESTION 3: What diagnostic tests and evaluations will be helpful in guiding P.C.'s therapy?

Basic laboratory and diagnostic tests should be quickly performed to exclude non-cerebrovascular causes of P.C.'s symptoms, such as metabolic or toxicologic derangement or infections. These tests include a routine serum chemistry profile (electrolytes, blood urea nitrogen, serum creatinine, hepatic enzymes, calcium, phosphorus, magnesium, and albumin), complete blood count, and toxicology screen. Coagulation studies, including a prothrombin time with international normalized ratio (INR) and partial thromboplastin time, should be performed to provide baseline values for potential anticoagulation or thrombolytic therapy. In addition, a thorough physical, neurologic, cardiovascular, and mental status examination should be performed. The neurologic examination will assist in the localization of the lesion in the CNS. The physical examination should include use of the NIHSS.[8] In addition to providing important information for diagnosis of his neurologic compromise, these tests will provide baseline data for ongoing assessment of P.C.'s progress and recovery.

P.C. must have a noncontrast head CT before initiation of any specific therapy for stroke. A follow-up CT or MRI is useful to determine the extent of neurologic damage resulting from the ischemic stroke.

CASE 61-1, QUESTION 4: What are the goals of therapy for AIS in P.C.?

The immediate goal is to reestablish adequate blood flow in the diseased cerebral vessels to salvage the ischemic penumbra and limit the expansion of the ischemic core. In addition, the acute goals include prevention of AIS complications such as hemorrhagic conversion, aspiration pneumonia, formation of venous thromboembolism, and brain swelling.

Longer range objectives are to prevent reocclusion, decrease the risk of a future ischemic stroke, and provide education and rehabilitation to allow return to normal functional status with minimal disability. Screening for depression and minimizing the risk of dementia are additional holistic long-term goals.[8]

The modified Rankin Scale (mRS) is the gold standard for measuring the degree of disability or dependence in the daily activities of people who have suffered a stroke.[25] It has become the most widely used clinical outcome measure for clinical trials evaluating therapy efficacy for AIS. The mRS ranges from 0 to 5, with 0 representing the absence of disability and 5 representing severe disability. A separate category of 6 is usually added for patients who expire. Functional status measured by mRS is typically assessed at discharge from the hospital and again at 90 days following discharge. The mRS score at 90 days is used as part of the standard performance outcome measure for the joint commission–certified comprehensive stroke centers in the United States.[26] Details about the mRS can be found in **Table 61-2**.

Table 61-2
Modified Rankin Score to Evaluate Functional Status Outcome After an Acute Ischemic Stroke

Label	Value	Interpretation
Independent Functional Status	0	**No symptoms**
	1	**No significant disability despite symptoms:** able to carry out all usual duties and activities
	2	**Slight disability:** unable to carry out all previous activities but able to look after own affairs unassisted
Dependent Functional Status	3	**Moderate disability:** requires some help but able to walk without assistance
	4	**Moderate severe disability:** unable to walk unassisted and unable to attend to own bodily needs without assistance
	5	**Severe disability:** bedridden, incontinent, and requiring constant nursing care and caregiver attention
Death	6

Therapy

INTRAVENOUS THROMBOLYSIS

CASE 61-2

Question 1: R.W. is an 84-year-old right-handed female with history of macular degeneration, spondylosis of lumbar region, and benign parotid gland neoplasm status post removal who presented to the ED for acute-onset slurred speech and right hand/arm weakness. The patient was last at her normal state of health at 7:30 AM when she was talking to her husband. She then got up to go to the bathroom around 7:45 to 8:00 AM and felt dizzy and unwell. She fell in the bathroom unwitnessed. Her husband called EMS, who noted that she was not moving her right side with right-sided facial asymmetry and had abnormal, aphasic speech. At present, the patient is having difficulty with history reporting. She states she has pain on the left shoulder from a recent fall, which limits her range of motion on that side. The patient has no history of neurologic disorders including strokes, mini strokes, seizures, and dementia. She has baseline vision loss related to her macular degeneration. She has no other baseline neurologic deficits. The patient has a history of arthritis and has had recent mechanical falls; most recently, she was seen in the ED 2 weeks before presentation for a mechanical fall in which her foot got stuck on a stair and she fell. The patient does not take aspirin, clopidogrel, or any anticoagulant. Her NIHSS was scored as 8 by the neurologist and her neurologic exam is documented for the following findings:

Mental status: Awake, oriented to person, not to place or time, unable to state her correct age, confused speech, able to follow simple commands but has difficulty with multistep commands, unable to describe the cookie theft scene or name items in the stroke booklet, although this may be due to visual limitations, seems to have difficulty naming items in the exam room, responds "yes" or "no" to questions not always appropriately, able to repeat short sentences but has difficulty with longer sentences.
Cranial nerves: Pupils are reactive to light; full visual fields; extraocular movements are intact; no dysarthria; mild right facial droop.
Motor: Moving all extremities antigravity with some resistance strength with encouragement, has motor neglect affecting the right upper and lower extremity that limits her movements. Drift of the right upper extremity.
Sensory: Decreased throughout the right side, sensory neglect of the right side.

Coordination: Has difficulty following commands to participate in coordination tasks.

Noncontrast CT of the head showed no acute hemorrhage, no acute or evolving infarct, white matter disease, and chronic infarct in the right hemisphere seen on prior CT obtained 2 weeks ago. CTA showed an area of cutoff, thrombus in the inferior branch of the left middle cerebral artery (MCA). CT-P showed a small core infarct (3) and a larger area of ischemic penumbra (14).

Her vital signs in the ED: temperature 98.60 °F (37 °C), heart rate 70 beats/minute (bpm), blood pressure 148/52, relevant laboratory point-of-care test for glucose 105 mg/dL, glycated hemoglobin 6.3%, platelet count 250,000 cells/L, INR 1.2.

Is R.W. a candidate for intravenous (IV) thrombolysis?

The critical primary event in a thromboembolic stroke is the development of an acute thrombus. Prospective cerebral angiography has demonstrated an arterial occlusion corresponding to the area of acute neurologic deficit in >90% of cases.[27] Occlusion of cerebral arteries does not cause complete ischemia because collateral circulation from other arterial sources provides unstable and incomplete circulation to the ischemic region of the brain.[28] When CBF is sustained in the range of 10 to 18 mL/100 g/minute, irreversible cellular damage may occur. Blood flow must be restored quickly after the event. Experimental studies in dogs and cats have shown that when CBF is restored within 2 to 3 hours, neurologic deficits are prevented.[29,30]

Thrombolytic agents are capable of reestablishing blood flow to ischemic regions of the brain and to limit the growth of the *ischemic penumbra*. The most important factor in successful thrombolytic therapy is early treatment. Door-to-needle (DTN) time is quality performance measure of stroke centers measuring the time of presentation to the ED to the time the infusion of thrombolytics is started. Current guidelines recommend a DTN time as fast as possible (eg, ≤60 minutes) and that stroke centers monitor the time to enhance the center's performance.[8] Pharmacists' involvement in stroke teams or in the ED have been shown to play a major role in improving DTN time.[31] In addition, to ensure safety of thrombolytics, the selection of appropriate candidates for thrombolysis is extremely

important and requires the correct neurologic evaluation by a specialized team. Current guidelines include a list of indication and contraindications found in table 8 of the guidelines for IV thrombolysis compared to the prior edition that listed inclusion and exclusion citeria.[8,32] All patients who meet eligibility criteria for IV thrombolysis should be offered such therapy, and the list of eligible patients became more inclusive in the most current version of the guidelines. **Table 61-3** lists indications and contradictions for patients with AIS who could be treated with IV thrombolysis, as adapted from table 8 from the current guidelines.[8] Before the initiation of IV thrombolysis, patients with high BP should have their BP lowered carefully to systolic blood pressure (SBP) <185 and diastolic blood pressure (DBP) <110 mm Hg (refer to **Table 61-4** and the discussion later on BP control).

Table 61-3

Eligibility Criteria for IV Alteplase Use in Treatment of Acute Stroke

Indication Criteria	Contraindication Criteria (No Benefit or Harm)
▪ Age 18 years and older ▪ Clinical diagnosis of stroke with clinically meaningful neurologic deficit ▪ Within 3–4.5 hours of AIS symptom onset or patient last known well or at baseline state ▪ Wake up with stroke and unknown time of onset and have a DW-MRI lesion smaller than one-third of MCA territory with no visible signal change on FLAIR ▪ Baseline noncontrast CT with no evidence of intracranial hemorrhage	▪ Mild nondisabling stroke (NIHSS 0–5) ▪ CT signs of intracranial hemorrhage, multilobar infarction, or symptoms of subarachnoid hemorrhage ▪ Active internal bleeding ▪ History of intracranial hemorrhage ▪ Intracranial neoplasm, aneurysm, or arteriovenous malformation ▪ Ischemic stroke or serious head injury within 3 months ▪ Systolic BP >185 mm Hg, diastolic BP >110 mm Hg ▪ Glucose <50 mg/dL or >400 mg/dL if unable to normalize ▪ Infective endocarditis given increased risk of ICH

	▪ Aortic arch dissection
	▪ Active bleeding diathesis including but not limited to:
	  ▪ Current use of anticoagulant with INR >1.7
	  ▪ Use of IV aspirin
	  ▪ Current use if direct thrombin inhibitors with elevated sensitive laboratory tests (such as aPTT, INR, ECT, TT, and factor Xa activity assay)
	  ▪ Heparin received in last 48 hours resulting in abnormally elevated aPTT or LMWH full treatment dose within the previous 24 hours
	  ▪ Platelet count <100,000/mm^3
	▪ *Pregnancy if risk outweighs benefit*
	▪ *GI or urinary tract hemorrhage within 3 weeks*

	Extended 3- to 4.5-hour window: ▪ Uncertain benefit NIHSS score >25 ▪ Taking an oral anticoagulant with INR >1.7 or any direct oral anticoagulants ▪ Imaging evidence of ischemic stroke involving more than one-third of MCA territory

AIS, acute ischemic stroke; aPTT, activated partial thromboplastin time; BP, blood pressure; CT, computed tomography; DW-MRI, diffusion-weighted magnetic resonance imaging; ECT, ecarin clotting time; FLAIR, fluid-attenuated inversion recovery; GI, gastrointestinal; ICH, intracranial hemorrhage; INR, international randomized ratio; IV, intravenous; LMWH, low-molecular-weight heparin; MCA, middle cerebral artery; NIHSS, National Institutes of Health Stroke Scale; TT, thrombin time.

Guidelines for the early management of patients with acute ischemic stroke: 2019 update to the 2018 guidelines for the early management of acute ischemic stroke: a guideline for healthcare professionals from the American Heart Association/American Stroke Association. *Stroke.* 2019;50(12):e344–e418 (full list of indications and contraindications found in Table 8).

Table 61-4
Management Guideline for Blood Pressure Treatment in Acute Ischemic Stroke

Treatment	Received Alteplase/Mechanical Thrombectomy	Did Not Receive Alteplase or Mechanical Thrombectomy
No treatment recommended	If BP is <185/110 mm Hg	If BP <220/120 mm Hg unless there is another specific medical condition
Nicardipine 5 mg/hour, titrate up by 2.5 mg/hour every 5–15 minutes (maximum 15 mg/hour) Labetalol 10–20 mg IV over 1–2 minutes, every 5 minutes may repeat to a maximum of 300 mg total, or labetalol 10 mg IV followed by continuous infusion 2–8 mg/minute Clevidipine 1–2 mg/hour, titrated by doubling the dose every 2–5 minutes until desired BP achieved (maximum 21 mg/hour)	If BP >185/110 mm Hg, goal is to lower below 185/105 mm Hg to limit risk of ICH before start of alteplase and to keep BP ≤180/105 mm Hg after alteplase for 24 hours	If systolic BP >220 mm Hg or diastolic 120–140 mm Hg
IV sodium nitroprusside 0.5 µg/kg/minute	If BP not controlled by abovementioned measures or if diastolic BP is >140 mm Hg	If not controlled or if diastolic BP >140 mm Hg

BP, blood pressure; ICH, intracranial hemorrhage; IV, intravenous.

Source: Powers WJ, Rabinstein AA, Ackerson T, et al. Guidelines for the early management of patients with acute ischemic stroke: 2019 update to the 2018 guidelines for the early management of acute ischemic stroke: a guideline for healthcare professionals from the American Heart Association/American Stroke Association. *Stroke.* 2019;50(12):e344–e418.

Several thrombolytics (streptokinase, alteplase, tenecteplase, reteplase, and urokinase) are available. However, only alteplase trials have shown benefits and improved outcomes.[33–36]

In three studies, streptokinase was used as the thrombolytic, and all of these studies were terminated early owing to high rates of mortality and ICH associated with streptokinase.[33,34,37] The rates of ICH ranged from 6% to 17% for patients receiving streptokinase compared with 0.6% to 3% for patients receiving placebo.

The National Institute of Neurological Disorders and Stroke (NINDS) alteplase trial[35] and the European Cooperative Acute Stroke Study (ECASS) I[36] used different doses, inclusion criteria, and treatment protocols. Both trials showed the benefit of alteplase in at least some outcome parameters. In the NINDS alteplase study, patients were enrolled within 3 hours of symptom onset using strict inclusion and exclusion criteria. When enrolled, patients received either IV tissue plasminogen activator (tPA) known as alteplase 0.9 mg/kg (maximal dose, 90 mg), with 10% of the dose given as a bolus for 1 minute and the remainder infused for 60 minutes, or placebo. In this study, there were no differences in the primary outcome defined as improvement by at least 4 points on the NIHSS score or complete resolution of neurologic deficit at 24 hours in responses between the placebo group and those who received IV tPA. However, at 3 months, patients who received IV tPA were 30% more likely to have minimal or no disability, as measured by the outcome scales. There was an 11% to 13% absolute increase in the number of patients with excellent outcomes and a corresponding decrease in the number of patients with severe neurologic impairment or death at 3 months. ICH occurred more frequently among patients receiving IV tPA (6.4%) than in patients receiving placebo (0.6%). Despite the increased incidence of ICH, outcomes remained better for patients receiving tPA. For the ECASS I trial, patients were enrolled within 6 hours of the onset of symptoms.[36] The treatment protocol consisted of IV tPA 1.1 mg/kg (maximal, 100 mg) or placebo. There was no difference in the primary outcome measures of functionality at 3 months. However, with target population analysis, there was a significant difference favoring tPA. Of patients treated with tPA, 41%

had minimal or no disability compared with 29% of patients treated with placebo. A variety of secondary outcome measures favored tPA. There was no difference in 30-day mortality rates, but 19.8% of patients treated with alteplase had major parenchymal hemorrhages compared with 6.5% of patients treated with placebo.

Since NINDS and ECASS-I, three subsequent trials, the ECASS-II[38] and Alteplase Thrombolysis for Acute Non-Interventional Therapy in Ischemic stroke (ATLANTIS A and B) found largely the same effects as NINDS when therapy was initiated in the ≤3-hour time period. The ECASS-II study used a tPA dose of 0.9 mg/kg and replicated the NINDS trial[38]; however, patients were enrolled up to 6 hours after the onset of stroke symptoms. This study found no difference between tPA and placebo. Too few patients were enrolled with stroke symptoms within 3 hours to reliably evaluate the influence of this variable on outcome.

Since NINDS, several trials have also investigated the use of IV tPA up to 6 hours after stroke onset. ECASS-I, ECASS-II, and ATLANTIS A and B all enrolled patients with an extended window use of tPA. None of these trials found individually a benefit; however, a pooled analysis suggested improved outcomes.[39] Hence, the ECASS-III study was conducted to evaluate the efficacy and safety of tPA administered using the NINDS tPA dose (0.9 mg/kg up to maximum of 90 mg), but it focused on the efficacy and safety of tPA administered 3 to 4.5 hours after the onset of symptoms.[40] A significantly greater number of patients receiving tPA had favorable outcomes on the mRS global disability scale compared with placebo (odds ratio [OR] 1.34; 95% confidence interval, 1.02–1.76). Although the rate of ICH was greater with tPA, mortality and reports of adverse events were similar between the two groups. When considering the use of tPA in the 3- to 4.5-hour window, the ECASS-III criteria should be followed (Table 61-3). In a large, randomized, placebo-controlled trial, the third International Stroke Trial (IST-3), which followed the NINDS dosing scheme for tPA, where patients were enrolled within 6 hours of symptoms onset, there was a significant improvement in functional outcome in the Oxford Handicap score (OR 1.27; 95% confidence interval, 1.10–1.47). However, there were more deaths at

7 days in the tPA group. IST-3 included patients age older than 80 years in comparison to ECASS-III and a broader BP eligibility. In summary, controlled trials have shown IV tPA to be beneficial for select patients with AIS who start treatment within 4.5 hours. For indicated patients (Table 61-3), once a CT ruled out a hemorrhage, IV tPA should be started within 4.5 hours of clearly defined symptoms. There are specific criteria to select patients for tPA eligibility if they present within 3 hours of onset of symptoms versus if they present up to 4.5 hours of symptoms (see Table 61-3).

Tenecteplase, a structurally modified alteplase at three points resulting in a more fibrin-specific agent with a better pharmacokinetic profile and longer duration of action compared to tPA, has been recently evaluated as an alternative to tPA for AIS.[41–44] IV tenecteplase is administered as a bolus dose with fewer steps for preparation and reconstitution as opposed to a 60-minute infusion of tPA, providing the former with an additional logistic advantage. Tenecteplase appears to have safety similar to that of tPA, but it is unclear if it is as effective as or superior to tPA. Indeed, IV tenecteplase (0.4 mg/kg bolus), in patients presenting within 4.5 hours of symptom onset of mild stroke (NIHSS score 0–7) was found at best to achieve similar functional outcomes at 90 days as assessed with mRS with tPA with similar rates of ICH.[44] Based on these trials, current guidelines suggest tenecteplase as an alternative to tPA in patients with minor neurologic impairment and no major intracranial occlusion.[8,45] In the tenecteplase versus tPA before thrombectomy for ischemic stroke (EXTEND-IA TNK) trial, patients with LVO and who are candidates for mechanical thrombectomy, IV tenecteplase 0.25 mg/kg (maximum 25 mg) administered within 4.5 hours showed at least noninferiority to alteplase and a statistically significant better reperfusion rate of >50% pre-CT–guided thrombectomy.[46] Based on the results of EXTEND-IA TNK, the current guidelines added a recommendation to select tenecteplase over alteplase before thrombectomy in patients without contraindications to IV thrombolysis who are also eligible for mechanical thrombectomy.

Finally, in patients who are awake with stroke symptoms or have an unclear time of onset >4.5 hours from last known well or at baseline, a diffusion-weighted (DW) MRI is recommended. If lesions are present and are smaller than one-third of the MCA territory and there is no evidence of abnormalities on fluid-attenuated inversion recovery (FLAIR) MRI sequence, in the absence of LVO, IV tPA is recommended.[8] Efficacy and Safety of MRI-Based Thrombolysis in Wake-Up Stroke (WAKE-UP) trial was investigated. The MRI-guided thrombolysis in patients with stroke with unknown time of onset led to better functional outcome and numerically more ICHs than placebo at 90 days.[47] In this randomized clinical trial, an mRS score 0 to 1 was achieved in 53.3% of the tPA group and 41.8% of the placebo group (P = .02). The median time from last known well to symptom recognition was about 7 hours and to tPA administration slightly >10 hours. Only 20% of the patients randomized had LVO of the intracranial carotid or proximal middle cerebral arteries. In addition, a recent meta-analysis also confirmed the WAKE-UP investigators' findings by combining the results of three other published trials that investigated MRI-guided tPA administration in unclear time of onset of stroke symptoms from last known well.[48]

R.W. is considered a candidate for IV tPA, because she presented to the ED within the 3-hour window of her stroke symptom onset, her NIHSS score was 8, and there was absence of obvious contraindications according to the current guidelines, as outlined in Table 61-3. Her total IV tPA dose will be 0.9 mg/kg, with 10% of the dose administered as an IV push over 1 minute followed by the reminder of the dose infused over 60 minutes. The DTN time should be recorded in the institution database for performance measure tracking. During and after receiving tPA, the patient should be monitored for the onset of adverse reactions associated with alteplase such as orolingual angioedema and ICH. The current guidelines recommend BP checks, neurologic examination, and angioedema screenings every 15 minutes for the first 2 hours after initiating alteplase and then every 30 minutes for 6 hours followed by every hour for 16 hours.[8] Orolingual angioedema is rare, and it is thought to occur by histamine release and increase in circulating

bradykinin induced by the activation of conversion of plasminogen to plasmin. If it occurs during tPA infusion, the infusion should stop immediately, and the American Heart Association/American Stroke Association (AHA/ASA) guidelines recommend rapid administration of methylprednisolone, diphenhydramine, and an IV histamine-2 blocker such as famotidine along with 0.3 mg intramuscular (IM) epinephrine if angioedema is not responsive to steroids. Icatibant, a selective bradykinin B_2 receptor antagonist or plasma–derived C1 esterase inhibitor are expensive alternatives that may need to be entertained if the patient fails to respond, given that tPA-mediated angioedema is most likely mediated by bradykinin. Alternatively, ecallantide, a kallikrein inhibitor that prevents the transformation of kininogen to bradykinin, may be considered as an option to target the angioedema associated with tPA.[49]

Symptomatic intracranial hemorrhage (sICH) that occurs within 24 hours of IV tPA administration is the most feared complication of IV thrombolysis. It can be treated with cryoprecipitate 10 units infused over 10 to 30 minutes, tranexamic acid 1000 mg IV over 10 minutes, or aminocaproic acid 4 to 5 g over 1 hour.[8,50,51]

CASE 61-2, QUESTION 2: What general supportive care interventions should be made for R.W.?

In addition to the general supportive therapy needed for a hospitalized patient, several issues are important to the proper management of R.W.

Assessing vital signs and ensuring stabilization of airway, breathing, and circulation is the initial part of the evaluation. Intubation and mechanical ventilation may be required to ensure adequate ventilation and to protect the airways from aspiration. Careful attention should be given to fluid and electrolyte control. Excessive hydration or inadequate sodium supplementation may result in hyponatremia, potentially causing cerebral edema. This can result in compression and displacement of brain tissue, which can disrupt cerebral perfusion. In addition, hyponatremia can produce

seizures, which increases the metabolic demand on compromised neurons. Thus, 0.9% saline or lactated Ringer are the preferred fluids in patients at risk for cerebral edema.[23]

Attention to body temperature needs to be given. Studies have shown that even small increases in temperature are associated with worse outcomes after acute stroke.[52,53] Hypothermia is neuroprotective, and a reduction in body temperature of 0.26 °F (−17.63 °C) can be beneficial in patients with stroke.[23,54] Use of antipyretics, such as acetaminophen, is advised to maintain normal or slightly subnormal body temperatures.

Another metabolic parameter that must be followed carefully is the serum glucose concentration, because hyperglycemia may adversely affect ischemic infarction outcomes. A review of multiple studies on the effects of hyperglycemia in acute stroke concluded that hyperglycemia results in poor outcomes and increased mortality.[55] If hyperglycemia is detected, appropriate insulin therapy should be initiated to keep the serum glucose concentration <140 mg/dL without causing hypoglycemia.[23]

The general daily needs of the patient should be assessed and provided on an as-needed basis. Attention should be provided to prevent deep venous thrombosis (DVT), decubitus ulcers, and delirium. Neurologic deficits will compromise the ability of many patients to adequately meet these needs, increasing the necessity for medical assistance.

ENDOVASCULAR INTERVENTIONS

CASE 61-2, QUESTION 3: What other reperfusion interventions might be considered for the acute treatment of stroke in R.W.?

A number of endovascular treatment options for ischemic stroke are available and include intra-arterial fibrinolytics, endovascular thrombectomy (EVT) with coil retrievers such as the Mechanical Emboli Removal in Cerebral Ischemia (MERCI) device or stent retrievers, combination intra-arterial thrombolytics with EVT, direct

aspiration thrombectomy, and emergency angioplasty and stenting. The most current guidelines recommend using the stent retrievers over coil retrievers.[8]

IV tPA can fail to achieve revascularization in patients with LVO such as the internal carotid artery or the MCA. R.W. has an MCA infarct (and, therefore, an LVO), and IV tPA could fail to achieve the revascularization goal; hence, R.W. should be considered for eligibility for EVT.

EVT has been evaluated alone or in combination with IV thrombolysis.

In patients with stroke secondary to occlusions in the proximal anterior intracranial circulation, EVT using a stent retriever device after receiving IV tPA significantly reduced the 90-day functional disability without increasing risk of ICH or mortality compared to IV alteplase monotherapy.[56] Similar results were also found in four other trials comparing endovascular therapy with IV thrombolytics to standard therapy with IV thrombolytics alone for documented large occlusions in the proximal anterior circulation. Intra-arterial thrombectomy reduced disability and improved outcomes.[57–60] These trials required angiographic confirmation by CT of an intracranial occlusion for eligibility, whereas earlier trials that did not require such confirmation or used older devices (MERCI® and Penumbra System®) did not find such benefit.[61–64]

The superiority of EVT combined with IV thrombolysis was shown in several randomized controlled trials.[56,58,60,65] Performing EVT within 6 hours of symptom onset doubles the rate of revascularization at 24 hours and mRS at 90 days when combined with tPA. Current guidelines recommend the combination of IV tPA in addition to EVT in patients who meet eligibility criteria for EVT. These include age 18 years or older, LVO demonstrated on CTA, Alberta Stroke Program Early Computed Tomography Score (ASPECTS) of ≥6, NIHSS score ≥6, and treatment initiated (groin puncture) within 6 hours of symptom onset.[8] The ASPECTS is a 10-point scoring tool that assesses early ischemic changes in the patient's initial noncontrast head CT. Lower scores indicate a great degree of

ischemic changes, whereas a score of 10 (the highest) indicates no ischemic changes.

In selected patients with AIS within 6 to 16 hours of last known normal who have LVO in the anterior circulation, EVT is recommended if they meet the eligibility criteria derived from two recent landmark trials that evaluated the extension window for EVT beyond 6 hours.[66,67] Despite the possibility for extended treatment windows for EVT, these procedures are not available outside of comprehensive stroke centers. Starting the IV tPA in smaller medical centers or community hospitals remains the best approach for the moment. Telemedicine or telestroke can facilitate connecting these smaller medical or community centers with comprehensive stroke centers to coordinate the transfer of patients after completion of the IV tPA infusion. Patients eligible for IV tPA should always receive tPA even if mechanical thrombectomy is being considered.[8]

Finally, intra-arterial thrombolytic administration requires an experienced stroke center and careful selection to identify patients who would benefit. As with IV thrombolysis, intra-arterial thrombolytics should be administered, within 6 hours of onset of symptoms, in patients with occlusions of the MCA who are not candidates for IV tPA. Although intra-arterial thrombolytics can be considered when IV tPA is predicted to fail (LVO) or is contraindicated, these therapies, if available to be administered by a skillful interventional neuroradiologist, should be considered. Lack of identification of optimal dose and evidence of effectiveness in occlusions outside of the MCA limit the widespread use of intra-arterial thrombolytics. Intra-arterial thrombolytics are no longer recommended as a first-line reperfusion strategy.[8]

Unfortunately for R.W., the location of the clot was deemed by the neurologist to be too distant to recommend EVT. Otherwise, the other eligibility criteria for EVT were met.

Case 61-2, Question 4: What BP goal should be targeted in R.W.?

Caution should be exercised in the acute management of R.W.'s BP. Decreasing the BP too rapidly will compromise CBF and expand the region of ischemia and infarction, whereas hypertension may place her at a greater risk for cerebral hemorrhage, especially when a thrombolytic agent is used. However, a study comparing treated and untreated patients who were hypertensive in association with an acute stroke failed to demonstrate any difference in outcomes between the groups.[68]

For patients with an SBP >185 mm Hg or a DBP >110 mm Hg, who are otherwise candidates for IV thrombolysis, IV labetalol, continuous infusion of nicardipine, or clevidipine should be used to reduce the BP to these goals before starting alteplase.[8] The decision to select one antihypertensive agent over another depends on the hospital formulary; concomitant heart rate favoring labetalol, for example; or agent availability to quickly administer in the ED. Continuous infusion of clevidipine or nicardipine may provide a more stable BP control over labetalol IV and, therefore, may be preferred after alteplase administration for a tighter control. If BP is not controlled with nicardipine, clevidipine, or labetalol or if DBP >140 mm Hg, IV sodium nitroprusside could be considered. After administration of tPA, SBP should be kept <180/105 mm Hg to limit the risk of ICH 24 hours post IV thrombolysis. BP should be monitored every 15 minutes for 2 hours from the start of IV tPA, then every 30 minutes for 6 hours, and then every hour for 16 hours.[8]

Similarly, in patients who are candidates for mechanical thrombectomy, targeting a BP of <180/105 mm Hg is recommended for the first 24 hours post the thrombectomy based on the results of two major trials.[8,66,67] Higher BPs within the first 24 hours of successful thrombectomy increased the risk of sICH, mortality, and the need for hemicraniectomy.[69] In a recent retrospective analysis of 217 patients, the 90-day clinical outcomes, mortality, and functional status pointed out that a moderate BP target of <160/90 mm Hg was reasonable in patients who achieved successful thrombectomy and is potentially more preferred.[70]

In all other patients who are not candidates for IV thrombolysis or mechanical thrombectomy, "permissive hypertension" up to 220/120

mm Hg is recommended to maintain perfusion to the brain. This means that BP will be permitted to go up to 220/120 mm Hg without antihypertensive agents being administered. If there is a clinical deterioration in the neurologic function associated with the reduction in BP, the infusion rate of the antihypertensive agent should be slowed, or the drug discontinued. Specific BP management recommendations are outlined in Table 61-4.

After the first 24 hours of stroke onset, maintenance antihypertensive therapy can then be initiated using an oral agent, such as thiazide diuretics, calcium channel antagonists, or angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin-receptor blockers (ARBs). The reader is referred to the more detailed discussion of hypertension management in Chapter 9, Essential Hypertension.

CASE 61-2, QUESTION 5: Should anticoagulation or antiplatelet agents be used acutely in R.W.?

Several studies have evaluated the use of anticoagulants in the treatment of acute strokes. However, most of these studies are poorly designed or underpowered to determine the efficacy of these agents.

HEPARIN AND HEPARINOIDS

Three studies have evaluated the use of heparin in acute stroke.[71–73] In one double-blind study, heparin doses were adjusted to maintain the activated partial thromboplastin time (aPTT) at 1.5 to 2 times control and continued for 7 days.[71] There were no significant differences in death at 7 days, no differences in functional ability 1 year after the stroke, and a greater mortality rate at 1 year for patients treated with heparin. Another study compared aspirin, and two doses of subcutaneous heparin (5000 IU or 12,500 IU bid) for patients with AIS.[72] There was no reduction in mortality or morbidity for patients receiving either dose of heparin. Heparin use has also been studied in progressing stroke (stroke with evolving neurologic

symptoms), and no benefit was demonstrated with its use.[73] No studies have demonstrated that heparin is useful in mitigating the neurologic effects of a stroke.

Low-molecular-weight heparins (LMWHs) and heparinoids have been evaluated in several studies for acute stroke. Two doses of nadroparin were compared with placebo in one randomized, double-blind, placebo-controlled trial.[74] There were no differences in death rates or functional ability at 3 months among the three treatment arms. However, at 6 months, patients receiving high-dose nadroparin (ie, 4100 anti-Xa IU bid) had improved function. A large randomized, placebo-controlled trial of dose-adjusted danaparoid, a low-molecular-weight heparinoid, did not demonstrate improvement in patients treated with danaparoid.[75] In addition, no improvements were observed in studies of dalteparin and certoparin.[76,77]Similar to heparin, LMWHs and heparinoids are not indicated in the acute treatment of stroke.

DVT and pulmonary embolism (PE) are common complications in patients following a stroke. Intermittent compression devices such as Venodynes, which prevent pooling of blood in the lower extremities, should be applied within 24 hours of admission to the hospital unless contraindicated. The incidences of DVT and PE were reduced in most studies in which patients received heparin, LMWHs, or heparinoids.[78]

Unfractionated heparin 5000 units subcutaneously twice daily (bid) or three times daily can be initiated in R.W. for DVT prophylaxis after 24 hours of IV tPA administration once a repeat head CT ruled out ICH. Heparin is considered an inexpensive and effective option compared to LMWHs.

ANTIPLATELETS

The risk of recurrent ischemic stroke is high in the first 2 weeks after AIS or TIA. Up to 80% of recurrent strokes occur within the 14 days of the index event.[79]

Aspirin

One study evaluated early administration of aspirin in acute stroke. The Chinese Acute Stroke Trial compared 160 mg/day of aspirin administered within 48 hours of the onset of stroke symptoms with placebo.[80] Patients who received aspirin had reduced early mortality rates, but there was no difference in the primary end point of death or dependency at discharge from the hospital. Two other studies did not demonstrate benefit with aspirin.[37,72] When data from these studies are combined, a slight beneficial effect of aspirin is seen with regard to reducing the risk of early stroke recurrence. Current recommendations are for aspirin 325 mg to be administered within 24 to 48 hours of the onset of stroke symptoms, except when alteplase is administered. When alteplase is given, aspirin should be given 24 to 48 hours after alteplase administration but still within 48 to 72 hours of onset of stroke symptoms.[8] In R.W., IV tPA was used; hence, aspirin should not be administered until at least 24 hours after the end of the alteplase infusion have lapsed and once a repeat head CT ruled out hemorrhagic conversion.

Other antiplatelets

There has been limited published evidence available for the usage of other antiplatelets such as clopidogrel or dipyridamole in the acute treatment of ischemic stroke. Small pilot studies suggested some utility to these antiplatelets without providing solid evidence of a clear benefit of the well-established aspirin in AIS treatment. Platelet glycoprotein IIb/IIIa inhibitors have also been studied in acute stroke. A placebo-controlled phase 2 trial of abciximab given within 24 hours of acute stroke showed a trend toward improved functionality in patients treated with abciximab, but the study was not powered to show the significance of this outcome.[81]

Combination of antiplatelets

In the Clopidogrel in High-Risk Patients with Acute Nondisabling Cerebrovascular Events (CHANCE) trial, the investigators randomized 5170 patients in a double-blind, placebo-controlled study within 24 hours of the onset of symptoms of a minor stroke or TIA to

an initial loading dose of 300 mg clopidogrel followed by 75 mg/day for 90 days with aspirin at a dose of 75 mg/day, or to placebo plus aspirin 75 mg for 90 days. This study conducted in China found that the combination was superior to aspirin in reducing the risk of stroke in the first 90 days. The patient selection did not include major stroke or patients who received IV thrombolysis.[82] In the Platelet-Oriented Inhibition in New TIA and Minor Ischemic Stroke (POINT) trial, results noted from CHANCE were replicated in a more diverse ethnic background.[83] Within 12 hours of symptom onset, clopidogrel at a loading dose of 600 mg on day 1, followed by 75 mg/day, plus aspirin (at a dose of 50–325 mg/day) for 21 days, compared to the same range of doses of aspirin alone resulted in absolute risk reduction of 1.5% and 30% relative risk reduction of major ischemic events in the combination arm. The risk of hemorrhage from the antiplatelet combination was higher than from the aspirin monotherapy at 90 days. Of note, the patients included in this study had mild strokes (NIHSS <4) or high-risk TIA and were not candidates for IV thrombolysis or endovascular therapy; therefore, the safety of the combination antiplatelets post IV thrombolysis remain not well studied. Finally, the combination of ticagrelor and aspirin has been recently evaluated in the Acute Stroke or Transient Ischaemic Attack Treated with Ticagrelor and ASA [acetylsalicylic acid] for Prevention of Stroke and Death (THALES) trial.[84] Patients with mild-to-moderate acute non-cardioembolic ischemic stroke (NIHSS score of ≤5) or TIA and who were not undergoing thrombolysis or thrombectomy were randomized to within 24 hours of symptom onset to receive a 30-day regimen of either ticagrelor (180-mg loading dose followed by 90 mg bid) plus aspirin (300–325 mg on the first day followed by 75–100 mg daily) or matching placebo plus aspirin. The risk of the composite of stroke or death within 30 days was lower with the combination compared to aspirin alone. Severe bleeding was more frequent with the combination therapy.

Based on these studies, in patients with mild stroke (NIHSS <5) or TIA and not receiving IV thrombolysis or EVT, a short 21- to 30-day regimen of dual antiplatelet therapy (clopidogrel + aspirin or

ticagrelor + aspirin) initiated within 24 hours of symptom onset may be considered more beneficial than is aspirin monotherapy if the patients have no contraindications to the combination therapy. Other combinations have not been evaluated acutely and not recommended for use.

Given that R.W. received IV thrombolysis, aspirin 325 mg followed by 81 mg monotherapy is the preferred option. Aspirin is typically started after 24 to 48 hours of administration of thrombolysis after a repeat head CT confirmed absence of hemorrhagic transformation.

Ischemic Stroke Education

Case 61-2, Question 6: What information and instruction should be given to R.W. regarding future stroke symptoms?

Early treatment of acute stroke with available or investigational drugs appears to be the most important factor in determining optimal outcome. Nearly every clinical trial demonstrating some benefit of pharmacotherapy for acute stroke has shown the greatest effect for patients who are treated within a few hours of the onset of stroke symptoms. Immediate detection of stroke symptoms and initiation of treatment are imperative. The primary rate-limiting step in diagnosis and provision of medical care is early recognition of stroke symptoms. Every patient who is at increased risk for stroke should be carefully instructed to seek emergent medical attention if they experience any weakness or paralysis, speech impairment, numbness, blurred vision or sudden loss of vision, or altered level of consciousness. These symptoms should be handled with the same urgency as the symptoms of a myocardial infarction. The pharmacist should ensure that R.W. and her caregivers know the symptoms of stroke and understand what to do if they occur.

Ischemic Stroke Complications

Case 61-2, Question 7: What complications associated with stroke might R.W. experience?

Agitation, delirium, stupor, coma, cerebral edema, and increased ICP are other acute symptoms that can be associated with ischemic stroke. These symptoms correlate with the specific blood vessels that are affected, and the development of these complications in R.W. would depend on the progression of her stroke.

Seizures may occur in up to 20% of patients with stroke. Pneumonia, pulmonary edema, cardiac arrest, DVT, and arrhythmias are commonly associated with ischemic stroke and should be managed as they occur. In R.W., these may occur soon after her stroke or be related to a rapidly developing neurologic event such as further infarction, hemorrhage, or severe cerebral edema. Pneumonia or DVTs are related primarily to inactivity, and the risk of these events will increase the longer R.W. remains immobile.[85]

Patients with stroke frequently experience psychological reactions. The most common psychiatric complication is depression, occurring in 30% to 50% of patients.[86]

The severity of depression varies from mild to major depressive episodes. If the depression interferes with recovery and the rehabilitative process, it should be managed with the use of a selective serotonin reuptake inhibitor or other appropriate agents.

Ischemic Stroke Prognosis

Case 61-2, Question 8: After 4 days in the hospital, R.W.'s neurologic status is stabilized. Will further neurologic improvements be realized?

Neurologic deficits in patients with stroke are not considered stable or fixed until at least 8 to 12 months have elapsed. During this time, neurologic function may return but rarely to normal. The prognosis after ischemic stroke depends on a variety of factors including age, hypertension, coma, cardiopulmonary complications,

hypoxia, and neurogenic hyperventilation. However, infarction of the MCA is associated with a poor chance for recovery. Physical and occupational therapy techniques involving restriction of activity in the unaffected limb or limbs have proved to be effective in patients regaining lost function. Therefore, it is possible that R.W. will experience further neurologic improvement.

Secondary Prevention After Ischemic Stroke or Transient Ischemic Attack

Case 61-2, Question 9: What antiplatelet or anticoagulation therapy would be recommended for secondary stroke prevention for R.W.?

ANTIPLATELET THERAPY FOR SECONDARY PREVENTION

Because platelets play a key role in the formation of atheromatous clots, various antiplatelet drugs, such as aspirin, combination aspirin/dipyridamole, ticlopidine, clopidogrel, and cilostazol, have been studied for secondary prevention. Cilostazol is the only agent not approved by the U.S. Food and Drug Administration (FDA) for secondary prevention of ischemic strokes and TIAs arising from non-cardioembolic origin. These agents generally work by either preventing the formation of thromboxane A_2 (TXA_2) or increasing the concentration of prostacyclin. These actions seek to reestablish the proper balance between these two substances, thus preventing the adhesion and aggregation of platelets (**Table 61-5**). An ~22% relative risk reduction of stroke, myocardial infarction, or death is noted with these agents compared to placebo in patients with prior TIA or stroke.[87] Aspirin, clopidogrel, or a combination aspirin/dipyridamole is considered first-line therapy based on the current guidelines for non-cardioembolic ischemic stroke and TIA secondary prevention.[5]

Table 61-5
Drugs for Preventing Transient Ischemic Attacks and Ischemic

Stroke

Drug	Action	Dose	Adverse Effects
Aspirin	Antiplatelet	50–325 mg/day	Diarrhea, gastric ulcer, GI upset
Dipyridamole	Antiplatelet (use in combination with aspirin)	200 mg sustained release twice daily with aspirin 50 mg bid	GI upset
Ticlopidine	Antiplatelet	500 mg/day	Diarrhea, neutropenia, thrombocytopenic purpura, rash
Ticagrelor	Antiplatelet	180 mg once followed by 90 mg bid	Bleeding, bradyarrhythmias, hyperuricemia thrombocytopenia
Clopidogrel	Antiplatelet	75 mg/day	Bleeding, thrombocytopenia, neutropenia
Cilostazol	Antiplatelet	100 mg bid	Headache, peripheral edema. Contraindicated in patients with congestive heart failure
Warfarin	Anticoagulant (only in patients with cardioembolic cause of stroke/TIA)	Titrate to goal INR 2–3 for most patients 2.5–3.5 with mitral mechanical valve	Bleeding, bruising, petechiae
Rivaroxaban	Anticoagulant (only in patients with cardioembolic cause of stroke/TIA)	If CrCl >15 mL/minute, 20 mg once daily with evening meal	Bleeding
Apixaban	Anticoagulant (only in patients with cardioembolic cause of stroke/TIA)	5 mg bid If SCr ≥1.5 mg/dL, 2.5 mg bid (if age >80 years or weight ≤60 kg)	Bleeding
Edoxaban	Anticoagulant (only in patients with cardioembolic cause of stroke/TIA)	60 mg daily If CrCl 15–50 mL/minute 30 mg daily	Do not use if CrCl >95 mL/minute as there is an increased risk of ischemic stroke
Dabigatran	Anticoagulant (only in patients with cardioembolic cause of stroke/TIA)	150 mg bid If CrCL 15–30 mL/minute: 75 mg bid	GI bleed

bid, two times daily; CrCl, creatinine clearance; GI, gastrointestinal; INR, international normalized ratio; SCr, serum creatinine; TIA, transient ischemic attacks.

Aspirin

The effectiveness of aspirin for secondary prevention of non-cardioembolic ischemic stroke and TIA is supported by evidence of high quality. At least 15 randomized trials, with 7 being placebo controlled, have studied aspirin alone or in combination with other antiplatelet drugs in the prevention of vascular events.[88–93]

Patients were enrolled in these studies for as long as 5 years after experiencing a vascular event (ie, TIA, stroke, unstable angina, or myocardial infarction). Follow-up periods lasted from 1 to 6 years. The incidence of ischemic stroke or TIA ranged from 7% to 23%: the patients treated with aspirin experienced an average 22% decrease in relative risk of a stroke compared with those receiving placebo. In 10 trials that considered only patients with TIA or stroke, there was a 24% relative risk reduction in the incidence of nonfatal stroke associated with the use of aspirin. The risk reduction rate is equal for males and females.[89,94]

Dosages of aspirin used in clinical trials have ranged from 30 to 1500 mg/day. In a meta-analysis of placebo-controlled studies comparing 900 to 1500 mg/day of aspirin with similar studies of 300 to 325 mg/day, there was a 23% reduction in the risk of cerebrovascular events for patients receiving 900 to 1500 mg/day and a 24% reduction in risk for patients receiving 300 to 325 mg/day.[87] A prospective comparison of aspirin doses in 3131 patients showed a 14.7% frequency of nonfatal stroke or nonfatal myocardial infarction in patients receiving 30 mg of aspirin a day and a 15.2% frequency in patients receiving 283 mg of aspirin a day, a nonsignificant difference between these two doses.[95] The Swedish Aspirin Low-Dose Trial showed an 18% reduction in stroke in patients taking 75 mg of aspirin daily compared with placebo.[96] Helgason et al. compared the effects of 325, 650, 975, and 1300 mg of aspirin a day in patients with stroke.[97] Platelet aggregation studies were performed to determine the effects of aspirin. Eighty percent of patients had complete suppression of aggregation at a daily dose of 325 mg, an additional 5% responded at 650 mg/day, only 1% more responded at 975 mg/day, and there was no further response at 1300 mg. As aspirin doses increase, so does the risk of gastrointestinal (GI) bleeding.[98]

The recommended dose for aspirin is 50 to 325 mg/day. The goal is to use the lowest effective aspirin dosage, thereby limiting the risk of GI adverse effects. In the United States, a dose of 81 mg aspirin is usually started.

Ticlopidine

Ticlopidine is an antiplatelet agent approved only for the prevention of TIA and stroke for patients with a prior cerebral thrombotic event. By inhibiting adenosine diphosphate (ADP)-induced platelet aggregation, its activity differs from that of aspirin. Although effective in reducing the risk of stroke, its use is limited by serious hematologic and GI adverse effects.[99,100]

Clopidogrel

Clopidogrel is chemically related to ticlopidine and works by inhibiting platelet aggregation induced by ADP. A randomized, double-blind, international trial (Clopidogrel vs Aspirin in Patients at Risk of Ischaemic Events [CAPRIE]) compared clopidogrel 75 mg/day with aspirin 325 mg/day.[101] Patients enrolled in the study had a history of atherosclerotic vascular disease manifested by recent ischemic stroke, myocardial infarction, or symptomatic peripheral vascular disease. Using intention-to-treat analysis, a 5.3% risk of an event in patients receiving clopidogrel and a 5.83% risk in patients receiving aspirin were observed. This represents a statistically significant relative risk reduction of 8.7%, favoring clopidogrel. On-treatment analysis showed a relative risk reduction of 9.4%, again in favor of clopidogrel. For patients whose primary condition for entry into CAPRIE was stroke, the relative risk reduction was 7.3%; however, this difference was not statistically significant. Patients receiving clopidogrel more frequently experienced rash and diarrhea compared with those receiving aspirin. Patients receiving aspirin were more frequently affected by upper GI distress, ICH, and GI hemorrhage. Significant reductions in neutrophils occurred in 0.10% of patients on clopidogrel and in 0.17% of patients on aspirin. Some cases of thrombocytopenia purpura are reported in the literature.[102]

Clopidogrel is as effective and safe as aspirin. Clopidogrel is an alternative to aspirin in secondary prevention of stroke.[5] Polymorphisms in the hepatic enzymes involved in the metabolism and activation of clopidogrel (cytochrome P450 [CYP] 1A2, CYP3A4, CYP2C19) or within the platelet $P2Y_{12}$ receptor may affect clopidogrel's antiplatelet therapy. Similarly, drug interactions affecting the CYP2C19 can lead to decreased effectiveness of clopidogrel. Commonly prescribed proton-pump inhibitors, such as omeprazole, have been suggested to decrease the efficacy of clopidogrel. It is suggested to avoid the combination of omeprazole and clopidogrel until more solid evidence is available.[5]

Aspirin/dipyridamole

Dipyridamole inhibits phosphodiesterase and augments prostacyclin-related platelet aggregation inhibition. Four large randomized clinical trials have evaluated the secondary prevention effect of the aspirin and dipyridamole combination among patients with stroke or TIAs. Two European studies have shown benefit with a combination of aspirin and dipyridamole. In the first study, a combination of aspirin 325 mg/day and immediate-release 75 mg dipyridamole three times per day was compared with placebo.[103] Results from this study showed that the combination reduced the combined risk of stroke and death by 33% and the risk of stroke by 38%. The Second European Stroke Prevention Study enrolled patients who had experienced a previous stroke or TIA and found that aspirin combined with dipyridamole was more effective than placebo, dipyridamole alone, and aspirin alone.[104]

A sustained-release formulation of dipyridamole was used for this study. A 37% relative risk reduction was found for the combination treatment, and a 23% relative risk reduction was found for aspirin alone. The dipyridamole dose for this study was 200 mg bid, and the aspirin dose was 25 mg bid. Absolute risk reduction was ~1.5% annually. Headache occurred more frequently in patients receiving dipyridamole alone or in combination with aspirin. Bleeding complications were less frequent in patients receiving dipyridamole compared with aspirin alone. As a result of these findings, a combination product of aspirin and dipyridamole is available. The combination of sustained-release dipyridamole and aspirin is an acceptable alternative for secondary prevention of stroke when initial secondary prevention has failed.

In the 2006 open-label European/Australian Stroke Prevention in Reversible Ischemia Trial (ESPRIT), with a mean follow-up of 3.5 years, the combination aspirin/dipyridamole was associated with an absolute risk reduction of 1% per year for the composite primary outcome of vascular mortality, nonfatal stroke, nonfatal myocardial infarction (MI), or major bleeding (13% vs 16%). Bleeding rates were similar between the two groups. Combination aspirin/dipyridamole was discontinued secondary to headaches in 8.8% of patients. Of

note, the aspirin dose ranged from 30 to 325 mg, and 83% of the patients took the extended-release formulation of dipyridamole.[105]

Clopidogrel was compared with the combination aspirin and extended-release dipyridamole in the noninferiority Prevention Regimen for Effectively Avoiding Second Strokes trial.[106] Among the patients with non-cardioembolic ischemic stroke who were followed up for a mean of 2.5 years, there was no difference in stroke rates between the two intervention arms. The risk of GI hemorrhage was higher in the aspirin plus extended dipyridamole group compared to clopidogrel (4.1% vs 3.6%). Clopidogrel was better tolerated with less bleeding and less headaches than was the combination.

Cilostazol

Cilostazol is a vasodilator and antiplatelet agent. It has action on intracellular cyclic adenosine monophosphate (AMP) and is a phosphodiesterase-3 inhibitor that is used mainly for intermittent claudication in patients with peripheral artery disease.[107] In studies conducted in Asia, cilostazol 100 mg bid was found to equally reduce the risk of vascular events compared to aspirin in non-cardioembolic stroke. However, headache, diarrhea, palpitations, dizziness, and tachycardia were more frequent with cilostazol than with aspirin, leading to more discontinuation in therapy (20% vs 12%).[108,109] Given the ventricular tachycardia risk associated with cilostazol, it is contraindicated in patients with heart failure.[107]

Aspirin combined with clopidogrel

A major study has compared clopidogrel 75 mg/day with the combination of clopidogrel 75 mg/day and aspirin 75 mg/day.[110] There was no difference in the risk of recurrent stroke or other cardiovascular outcomes between the groups, but the combination therapy group had a significant increase in life-threatening bleeding. Some individuals may be resistant to aspirin's effects on platelets.[111] Although poorly understood and studied, aspirin resistance may be related to the presence of extra platelet sources of TXA_2 and an interaction with over-the-counter nonsteroidal anti-inflammatory

drugs or high levels of circulating 11-dehydro-thromboxane B_2. Cyclooxygenase-2 expression is induced during human megakaryopoiesis and characterizes newly formed platelets.[112–114] There are no data to suggest that increasing the aspirin dose will overcome possible resistance to the antiplatelet effects of aspirin, but it is clear that an increased dose of aspirin increases the risk of major bleeding.

Warfarin and oral anticoagulants

Large, randomized trials have compared oral anticoagulants with aspirin in the secondary prevention of stroke and TIA. In one study, aspirin 30 mg/day was compared with oral anticoagulants in doses adjusted to maintain an INR between 3.0 and 4.5.[115] This study was terminated early when the mortality rate attributable to major bleeding events in the anticoagulant group was double the rate in the aspirin group. In this study, there was no difference between anticoagulants and aspirin in the frequency of stroke. A second study compared warfarin, dosed to maintain the INR between 1.4 and 2.8, and aspirin 325 mg/day.[116] Results from this study did not demonstrate a significant difference between aspirin and warfarin with regard to the prevention of stroke or major hemorrhagic events. However, minor hemorrhages were significantly more frequent among patients receiving warfarin. A third study was terminated early because of safety concerns in the warfarin arm of the study.[117] The target INR for this study was 2 to 3 in the warfarin arm compared with that in the aspirin arm. The study was stopped owing to significantly higher rates of adverse events in individuals receiving warfarin and no difference in the risk of stroke. Events including major hemorrhage, myocardial infarction, or sudden death, and overall death were increased in those receiving warfarin. Warfarin is not generally recommended for secondary prevention of non-cardioembolic stroke. In secondary prevention of cardioembolic stroke originating from atrial fibrillation, in patients with CHA_2DS_2-VAsc score ≥2 (see **Table 61-6** for the calculation of $CHAD_2S_2$-VASc score), warfarin or the are preferred first-line therapy.[118,119] The

reader is referred to Chapter 15, Cardiac Arrhythmias for further discussion of stroke prevention in atrial fibrillation. The timing of beginning oral anticoagulants is recommended between 4 and 14 days after the onset of neurologic symptoms.[8]

Table 61-6

CHA_2DS_2-VAsc Score: Secondary Stroke Prevention in Atrial Fibrillation

CHA_2DS_2-VAsc score *Add points for the following items. If score is <2, aspirin can be considered. If score is ≥2, anticoagulants (warfarin, apixaban, rivaroxaban, edoxaban) are recommended.*
Congestive heart failure = 1 point
Hypertension = 1 point
Age >75 years = 2 points Age 65–74 years = 1 point
Diabetes mellitus = 1 point
Prior stroke or TIA = 2 points
Vascular disease (eg, peripheral artery disease, myocardial infarction, aortic plaque) = 1 point
Sex category (ie, female) = 1 point

TIA, transient ischemic attack.

Surgical Interventions for Secondary Prevention

Carotid endarterectomy (CEA) and carotid artery angioplasty and stenting (CAS) are available to prevent ischemic stroke or TIAs. These are designed to either remove the source of an embolism or improve circulation to ischemic areas of the brain.

CAROTID ENDARTERECTOMY

CEA is a common surgical procedure for correcting atheromatous lesions responsible for causing a TIA or an ischemic stroke. In this procedure, the carotid artery is surgically exposed, and the atheromatous plaque is excised. CEA combined with pharmacotherapy is considered the first-line option for patients with a high-grade (>70% angiographic stenosis) atherosclerotic carotid stenosis.[5] Other patients do not benefit as much from such procedures, and the benefit does not outweigh the risks. CEA is most effective for patients with an ulcerated lesion or a stenotic clot that occludes >70% of blood flow in the ipsilateral carotid artery and who experience symptoms of a TIA or stroke. Use of CEA in these patients may result in a 60% reduction in stroke risk during the subsequent 2 years.[120] Of six to eight patients treated with CEA, one stroke will be prevented within 2 years.[121] The use of CEA in other patient groups must be balanced with the risk of the procedure and life expectancy.[122] CEA is beneficial in patients with 50% to 69% stenosis of the carotid artery, and the procedure should be done within 2 weeks of a TIA or stroke.[5] Finally, CEA is not indicated in patients who have permanent neurologic deficits or total occlusion of the carotid artery.

Aspirin also has been used for the prevention of restenosis after CEA. During the first year after CEA, 25% of patients will redevelop a stenotic lesion, with more than half of these causing a >50% reduction in carotid blood flow.[95] Initial studies indicated that combination therapy with aspirin 325 mg/day and dipyridamole 75 mg three times a day would decrease the rate of restenosis. However, a subsequent randomized, placebo-controlled study using this regimen in post-CEA patients did not substantiate the earlier findings.[123] A combination of clopidogrel with aspirin has been shown to reduce postoperative ischemic events.[124]

CAROTID ARTERY ANGIOPLASTY AND STENTING

As an alternative to CEA, carotid artery angioplasty and stenting (CAS) can also improve blood flow through the placement of a stent

in a stenosed artery.[125] This is a less invasive procedure associated with less patient discomfort and a shorter recovery time. During this procedure, a catheter with a small, deflated balloon is placed in the stenosed artery, and the atherosclerotic lesion is pressed into the arterial wall when the balloon is inflated. A small, plastic tube stent is placed in the artery to prevent the vessel from collapsing at the site of the lesion. The initial study of this procedure was halted because of poor outcomes.[126] Subsequently, two studies have shown that CAS is not inferior to CEA.[127,128] CAS can be used in patients who are not candidates for CEA. CEA and CAS are typically recommended to be performed between 48 and 72 hours after initial AIS in eligible patients.[8] Noninvasive imaging obtained within 24 hours of AIS can help guide future CEA or CAS. After CAS, dual antiplatelet therapy with clopidogrel and aspirin is needed for 3 months, followed by a single antiplatelet agent thereafter.[129]

SPONTANEOUS INTRACEREBRAL HEMORRHAGE

Clinical Presentation and Treatment

CASE 61-3

QUESTION 1: S.P. is a 58-year-old male who was sitting at home watching television with his wife when he developed confusion, nausea, severe headache, and right arm weakness. His wife immediately calls for an ambulance; by the time the paramedics arrive, S.P. is slumped in his chair and unresponsive. Significant past medical history includes poorly controlled hypertension, atrial fibrillation, and osteoarthritis. He takes lisinopril 10 mg by mouth daily, warfarin 4 mg by mouth daily, and acetaminophen 1000 mg by mouth three times daily for these conditions. Upon presentation to the ED, his BP is 184/114 mm Hg. A CT scan shows an ICH. Key electrolyte concentrations, coagulation studies, and blood counts are within normal limits except for an INR of 4.8 and a blood glucose level of 194 mg/dL. S.P.'s neurologic symptoms and the appearance of blood on his CT scan are consistent with a diagnosis of ICH.

What risk factors for spontaneous ICH does S.P. have?

S.P.'s uncontrolled hypertension and his use of warfarin have increased his risk of ICH.[130] Specifically, use of warfarin increases the risk of ICH by two to five times depending on the degree of anticoagulation.[131,132] Patients such as S.P. who are taking warfarin before ICH and present with an INR >3 are at greater risk for developing larger hematomas, which are associated with worse outcomes, compared to those taking warfarin and presenting with a lower INR.[133,134] Patients taking oral anticoagulants are also at greater risk of death after ICH versus those not taking anticoagulants.[131] Other drugs that may increase the risk of ICH include target-specific agents such as DOACs, heparin, LMWHs, fondaparinux, and other parenteral anticoagulants; aspirin and other antiplatelet agents; selective serotonin reuptake inhibitors; and sympathomimetics, such as amphetamines, phenylpropanolamine, cocaine, and caffeine-containing medications.[135–139] Additional risk factors for nontraumatic ICH include advanced age, history of stroke, diabetes, smoking, excessive alcohol consumption, African American ethnicity, and low cholesterol levels, especially in the absence of HMG-CoA reductase inhibitor use.[140,141] Genetic predisposition does not play a role in most hemorrhagic strokes except for those caused by AVMs.

Case 61-3, Question 2: What are the key principles of therapy in patients presenting with spontaneous ICH?

Initial management of spontaneous ICH involves (a) preventing hematoma expansion and (b) preventing and managing elevated ICP.

To minimize hematoma expansion, anticoagulants should be reversed immediately in patients such as S.P. who present with drug-induced coagulopathies, and elevated BP should be carefully managed. Methods for preventing and managing elevated ICP include avoiding hypotonic fluids as well as medical and surgical

methods. Ancillary therapies including treatment of fever and avoiding hypoglycemia and hyperglycemia are also suggested. Recombinant factor VIIs have been studied in patients with ICH but have not been associated with benefits in patient-centered outcomes.[142]

Case 61-3, Question 3: What pharmacotherapy should be initiated to reverse S.P.'s anticoagulant-induced coagulopathy?

Up to 20% of patients with ICH present with a drug-induced coagulopathy, as S.P. did.[143,144] Because hematoma growth within the first 24 hours of ICH is directly associated with worse outcomes and reversal of warfarin-induced coagulopathies within 4 hours of ICH has been shown to limit hematoma expansion, it is important to reverse coagulopathies in a timely manner.[145,146] All anticoagulant and antiplatelet medications should be immediately discontinued, and agents should be administered to remove the anticoagulant medication from the body and reverse its effect.[147] Although S.P. was using warfarin for the prevention of ischemic stroke in the setting of atrial fibrillation, because of his acute ICH, the benefit of reversing the warfarin to improve neurologic outcome greatly outweighs the short-term risk of ischemic stroke resulting from anticoagulant reversal. If a patient has taken an oral anticoagulant within the past 2 hours, activated charcoal may be considered to prevent absorption; however, it is important to ensure the patient can tolerate enteral administration. Historically, fresh frozen plasma (FFP) has been used to reverse warfarin-induced coagulopathies in patients such as S.P.; however, because they have fewer complications and may be administered more rapidly, prothrombin complex concentrates (PCCs) have become the preferred agents to rapidly reverse warfarin-induced anticoagulation.[147] FFP contains all the clotting factors depleted by warfarin but can take several hours to thaw and administer and may be associated with pulmonary complications and edema because of the volume required. In contrast, PCCs may reverse the INR within minutes because they can be administered

more rapidly. Use of PCCs has been shown to more effectively limit hematoma expansion compared to FFP.[148,149] Three-factor PCCs contain factors II, IX, and X, whereas four-factor PCCs also include factor VII. Four-factor PCCs are generally preferred in the setting of ICH and coagulopathy due to warfarin or DOACs because they have all of the vitamin K–dependent clotting factors and other clotting factors overall. Because the effect of PCC and FFP is short-lived, patients with warfarin-induced coagulopathy should concomitantly receive 10 mg of IV vitamin K (phytonadione) by slow infusion.[150] INR should be checked after administration of PCC and serially thereafter to ensure it is not >1.4. It is important to note that because most PCC formulations are compounded with heparin, they may be contraindicated in patients with a recent history of heparin-induced thrombocytopenia.

DOACs are used more often nowadays to prevent stroke in patients with nonvalvular atrial fibrillation.[151–153] Similar to warfarin-induced coagulopathy, rapid reversal is indicated in patients who present with ICH after using one of these agents. If the patient was taking dabigatran, the anti-dabigatran monoclonal antibody fragment, idarucizumab, should be used for reversal. Dabigatran may also be removed through hemodialysis, although establishing vascular access may be challenging or impractical in patients with active bleeding. Rivaroxaban, apixaban, and edoxaban may be reversed with andexanet alfa or PCCs. Andexanet alfa is an inactive version of factor Xa that acts as a “decoy” and binds to the DOAC, thus preventing it from binding to factor Xa and exerting an anticoagulant effect. It was approved based on a single-arm study that demonstrated good hemostasis and reduction in anti-factor Xa activity after patients who had taken a direct-acting oral anticoagulant were given andexanet alfa; however, it was not compared to a PCC.[154] PCCs have been studied for reversal of direct-acting oral anticoagulants in a number of observational studies.[155,156] Because andexanet alfa and PCCs have not been rigorously compared to one another and because patient-centered outcomes have not been evaluated in large studies, either may be considered for reversal of coagulopathies in patients presenting with

ICH after taking DOACs.[157,158] It is important to note that both andexanet alfa and PCCs may predispose to thrombotic events, so clinicians should make a careful patient-specific decision regarding their use.

As with warfarin-induced coagulopathies, reversal agents should be administered promptly when indicated, and activated charcoal should be considered.

Other drug-induced ICHs may occur in patients receiving heparin, LMWHs, the parenteral factor Xa inhibitor fondaparinux, and antiplatelet agents such as aspirin and clopidogrel. Protamine sulfate may be used for the reversal of heparin and LMWH, whereas fondaparinux activity may be antagonized with PCCs. Limited evidence suggests that desmopressin may limit hematoma expansion in patients taking antiplatelet agents who develop ICH, but platelet infusions have not been shown to improve patient-centered outcomes.[50,159,160]

To reverse his warfarin-induced coagulopathy, current guidelines suggest that S.P. should receive a weight-based dose of a PCC product and 10 mg IV vitamin K by slow IV infusion.[50] The role of fixed doses of PCCs for vitamin K–antagonist reversal is being investigated. Studies to date indicate that fixed dosing shortens time to administration but may be associated with the need to repeat PCC administration and INR reversal failure in patients presenting with especially elevated INRs.[161]

Case 61-3, Question 4: How should S.P.'s acute hypertension be managed?

Excessive hypertension may expose patients with ICH to elevated risk of hematoma expansion, neurologic deterioration, and worse outcomes.[162,163] Lower BPs have been suggested to potentially worsen prognosis.[164] Some studies have shown that rapid BP reduction to an SBP <140 mm Hg is safe in patients with ICH presenting with hypertension.[165–168] However, more recent large trials that evaluated SBP lowering to <140 mm Hg versus maintaining an SBP between 140 and 179 mm Hg after ICH failed to show a

difference in death and severe disability, and a study in patients presenting with ICH and SBP >220 mm Hg demonstrated worse outcomes with BP management with a goal of 100 to 139 mm Hg versus 140 to 179 mm Hg.[169]

Based on these studies, SBP should be lowered to ~140 mm Hg in patients presenting with an SBP of 150 to 220 mm Hg who do not have contraindications to antihypertensive therapy. In patients presenting with an SBP >220 mm Hg, it is recommended to initiate aggressive antihypertensive therapy with an IV infusion and to carefully monitor the patient.[147] These patients may require a somewhat higher SBP goal range because their cerebral vasculature may have adapted somewhat to chronic high BPs.

Nicardipine and labetalol are the most commonly used antihypertensive agents in patients with ICH, but hydralazine, nitroprusside, or nitroglycerin may be considered depending on the clinical situation. If labetalol is used to control acute BP, it should be administered as IV boluses, potentially in combination with an IV infusion. Nicardipine is only administered as an IV infusion.

S.P.'s BP is elevated, so IV antihypertensive therapy is indicated. It would be appropriate to initiate an IV nicardipine infusion at 5 mg/hour and titrate every 5 minutes to achieve an SBP of ~140 mm Hg in S.P.

Case 61-3, Question 5: Hours after admission, S.P.'s mental status worsens, likely because of severely elevated ICPs. What therapy should S.P. receive for his elevated ICP?

Elevated ICP refers to excessive pressure inside the intracranial vault that may occur in patients with severe hemorrhagic and ischemic strokes as well as in those suffering from traumatic brain injury, brain tumors, hydrocephalus, and hepatic encephalopathy. It can lead to brain hypoxemia and cause herniation. S.P.'s worsened mental status may be consistent with elevated ICP. Other symptoms of elevated ICP include headache, vomiting, cranial nerve palsies,

and the combination of bradycardia, respiratory depression, and hypertension.

In patients with neurologic emergencies, such as S.P., hypotonic fluids such as dextrose 5% in water should be avoided in favor of isotonic fluids such as 0.9% sodium chloride (normal saline) and lactated Ringer because hypotonic fluids can exacerbate cerebral edema and worsen ICP.[148] When considering the fluids patients are receiving, it is important to evaluate both maintenance fluids and the fluids in which IV medications are diluted. In patients with elevated ICPs, IV medications should be diluted in 0.9% sodium chloride rather than dextrose 5% in water or other hypotonic fluids whenever possible.

Treatment of elevated ICP involves patient care measures, pharmacotherapy, and surgical interventions. First, the head of the bed should be elevated to at least 30° once it is clear that S.P. is not hypovolemic in order to minimize blood and fluid accumulation in the brain. Hyperventilation (increasing the patient's respiratory rate and/or the volume of air he breathes with each respiration) with a $Paco_2$ goal of <30 mm Hg may be considered for a very short time in S.P. until other interventions can be implemented. Because the low $Paco_2$ induced by hyperventilation leads to a lower CBF, this will lower ICP, but hyperventilation should not be continued long-term because reduced CBF may lead to brain hypoxia.

S.P. should receive analgesic medications, such as fentanyl. Sedatives, such as propofol, should also be administered.[148] Hyperosmolar agents, including IV hypertonic sodium chloride, hypertonic sodium acetate, or mannitol, dosed at 0.25 to 1 g/kg every 4 to 6 hours, may be considered to establish an osmotic gradient that can facilitate the movement of fluid out of the brain, thus reducing ICP.[147,170,171] The patient's osmolar gap, electrolytes, acid–base status, and renal function should be monitored closely when using these agents. Clinicians may place an ICP monitor or utilize neurologic exams to guide treatment with hyperosmolar agents. If an ICP monitor is used, hyperosmolar therapy would be indicated to maintain an ICP of <20 mm Hg, whereas if an ICP

monitor is not utilized, a worsening in neurologic exam consistent with elevated ICP would warrant therapy. If S.P. continues to exhibit elevated ICPs after hyperosmolar therapy and adequate analgesia and sedation, a continuous infusion of a neuromuscular blocking agent may be considered. One last-line measure that may be considered is the use of a barbiturate coma; however, side effects, such as hypotension, cardiac depression, and ileus, as well as limited utility complicate these strategies. Lowering a patient's body temperature (therapeutic hypothermia) to reduce ICP has been studied, although efficacy remains dubious, and so it is not considered the standard of care but may be used as a salvage therapy in carefully selected patients.[172]

In patients who develop hydrocephalus because of an ICH or another condition, a ventriculostomy may be employed. A ventriculostomy is a surgically placed drain that resides in the ventricle and is used to drain CSF. Finally, open craniotomy, or removal of a portion of the skull, in the area of edema, may be considered in highly selected situations; however, the efficacy of this approach is questionable in many patients.

Case 61-3, Question 6: What other ancillary therapies may be appropriate for S.P.?

S.P. may benefit from (a) maintenance of normothermia with antipyretics and nonpharmacologic cooling strategy if he develops a fever and (b) avoiding hypoglycemia and excessive hyperglycemia.

Although the clinical benefit of antipyretic therapy has not been clearly established in ICH, fever is associated with a worse prognosis.[173] It is recommended that S.P.'s body temperature should be monitored and antipyretics and nonpharmacologic cooling strategies may be employed to achieve normothermia.[147]

Both hypoglycemia and hyperglycemia should be avoided in hemorrhagic stroke. Hypoglycemia can directly lead to neurologic injury, whereas hyperglycemia is associated with worsened neurologic outcome after a stroke. Considering that his blood

glucose is markedly elevated, S.P. should be initiated on an insulin regimen in accordance with institutional policies.

Seizures can complicate ~16% of all strokes and may be difficult to observe because they are often nonconvulsive.[147,174] However, because studies of prophylactic antiepileptic therapy have failed to demonstrate consistent benefit and have sometimes indicated harm,[175] current guidelines do not recommend routine seizure prophylaxis.[147] Antiepileptic therapy should be initiated promptly if a patient develops seizures during or after the development of an ICH.

Case 61-3, Question 7: What secondary prevention strategies should be recommended for S.P. after he recovers from his ICH?

For S.P. and any patient who has suffered an ICH, key modifiable risk factors that should be addressed upon stabilization include maintaining BP at <130/80 mm Hg, smoking cessation, treating sleep apnea, avoiding excessive alcohol use, and abstaining from cocaine and other illicit drugs.[147,174] The optimal duration of oral anticoagulant cessation in patients with spontaneous ICH is unclear; however, these agents should be held for at least 4 weeks after the development of ICH.[147]

REHABILITATION

CASE 61-4

Question 1: Patient J.A. has had a stroke and has received appropriate acute care. He is ready to be discharged from the hospital but still has trouble walking, talking, and performing activities of daily living.

For patients who require rehabilitative care after hospital treatment of an ischemic or hemorrhagic stroke, what interventions will aid their recovery?

Patients who have suffered ischemic and hemorrhagic strokes often require long-term rehabilitation after their acute treatment.

Rehabilitation is directed at managing daily functions, enhancing existing neurologic function, and attempting to regain lost function. Considerations for daily functions include activities of daily living and bowel and bladder management through balanced pharmacologic interventions. Efforts should be made to allow patients to function independently with activities of daily living and manage the psychological effects of stroke. Enhancement of current neurologic function and minimizing depression include elimination of drugs that may compromise patients' memory and mental function. These include benzodiazepines, major tranquilizers, and sedating antiepileptic drugs.

Localized spasticity is a common complication after strokes. Spasticity affecting a single limb frequently responds to regional motor nerve blocks with botulinum toxin. Aggressive physical therapy is also essential to the management of spasticity. Systemic antispasticity agents such as diazepam, baclofen, or dantrolene sodium are not used routinely because of the risk of toxicity. They are used only when spasticity involves multiple parts of the body or is unresponsive to other therapies.

Other less common impediments to patients' recovery after stroke include decubitus ulcers, hypercalcemia, and heterotopic ossification (eg, the laying down and calcification of a bone matrix in muscle surrounding major joints). Prevention through meticulous skincare is the key to the management of pressure ulcers. Mobilizing patients as soon as possible after stroke can prevent hypercalcemia and heterotopic ossification.

Principles of Infectious Diseases

Joshua A. Garcia and B. Joseph Guglielmo

CORE PRINCIPLES		CHAPTER CASES
1	Although acute infection generally is associated with an increased white blood cell count, fever, and localizing signs, these symptoms may be absent in less severe disease. More severe infection, including sepsis, may be associated with hypotension, disseminated intravascular coagulation, and end-organ dysfunction.	**Case 62-1 (Questions 1, 2), Figure 62-1**
2	Other disease states, particularly autoimmune disease and malignancy, may mimic infectious diseases. Although it should be considered a diagnosis of exclusion, drug-induced fever should be ruled out, particularly in patients without other classic signs and symptoms of infection.	**Case 62-1 (Question 3)**

3	Site-specific signs and symptoms and host factors generally predict the most likely pathogens, and empirical antimicrobial therapy should be directed against these organisms. Rapid detection tests improve the efficiency of identifying a pathogen; however, they are more costly than traditional methodology.	**Case 62-1 (Questions 4, 5), Tables 62-1, 62-2**
4	Isolation of an organism may reflect infection; however, colonization and contamination must be ruled out to avoid unnecessary antimicrobial exposure. Once a pathogen is identified, susceptibility tests, particularly disk diffusion or broth dilution, can demonstrate the most active antimicrobial agents.	**Case 62-1 (Questions 6, 7), Tables 62-3–62-7**
5	Once the site of infection is confirmed and the likely pathogens are identified, drug distribution to the site of infection, dosage, route of administration, antimicrobial toxicity, side effects, and costs, must be considered before selection of therapy. Therapy should be tailored to the narrowest-spectrum agents and the shortest effective duration of therapy to minimize bacterial resistance and superinfection.	**Case 62-1 (Questions 8–10), Table 62-8**
6	Antimicrobial dosing should reflect the site of infection, route of elimination, and	**Case 62-1 (Questions 11–13), Table 62-9**

	pharmacokinetics and pharmacodynamics.	
7	Antimicrobial failure may be related to pharmacologic factors (inadequate dosing, insufficient penetration to the site of infection, and inadequate duration) and host factors (presence of prosthetic material, undrained focus of infection, and immune status). Adjunct therapies, including pressors and volume repletion, may improve outcomes in patients who are critically ill.	**Case 62-1 (Questions 14–17)**

INTRODUCTION

The appropriate choice, dose, and duration of antimicrobial therapy are based on several factors. Before initiating therapy, confirmation of an infectious versus noninfectious process must take place. Once infection has been documented, the most likely site must be identified, and signs and symptoms (eg, erythema associated with cellulitis) generally direct the clinician to the likely source. Because certain pathogens are known to be associated with a specific site of infection, empirical therapy often is directed against these organisms. Additional laboratory tests, including the Gram stain, serologic analysis, and antimicrobial susceptibility testing, generally identify the primary pathogen and most active agents. Spectrum of activity, established clinical efficacy, adverse effect profile, pharmacokinetic disposition, and cost considerations ultimately guide the choice of therapy. Once an agent has been selected, the dosage and duration should be based on the size of the patient, site of infection, route of elimination, and other factors.

ESTABLISHING THE PRESENCE OF AN INFECTION

CASE 62-1

QUESTION 1: R.G., a 63-year-old, 154.32 pounds (70 kg) male in the intensive care unit (ICU) underwent emergency resection of his large bowel. He has been mechanically ventilated throughout his postoperative course. On day 20 of his hospital stay, R.G. suddenly becomes confused; his blood pressure (BP) drops to 70/30 mm Hg, with a heart rate of 130 beats/minute. His extremities are cold to the touch, and he presents with circumoral pallor. His temperature spikes to 104 °F (40 °C) (axillary), and his respiratory rate is 24 breaths/minute. Copious amounts of yellow-green secretions are suctioned from his endotracheal tube.

Physical examination reveals sinus tachycardia with no rubs or murmurs. Rhonchi with decreased breath sounds are observed upon auscultation. The abdomen is distended, and R.G. experiences new abdominal pain. No bowel sounds can be heard, and the stool is guaiac positive. Urine output from the urinary catheter has been 10 mL/hour for the past 2 hours. Erythema is noted around the central venous catheter.

A chest radiograph demonstrates bilateral lower lobe infiltrates, and urinalysis reveals >50 white blood cells/high-power field (WBC/HPF) (normal <10), few casts (normal, none), and a specific gravity of 1.015. Blood, endotracheal aspirate, and urine cultures are pending. Other laboratory values include the following:

Sodium (Na), 131 mEq/L (normal, 135–147)
Potassium (K), 4.1 mEq/L (normal, 3.5–5)
Chloride (Cl), 110 mEq/L (normal, 95–105)
CO_2, 16 mEq/L (normal, 20–29)
Blood urea nitrogen (BUN), 58 mg/dL (normal, 8–18)
Serum creatinine (SCr), 3.8 mg/dL (increased from 0.9 mg/dL at admission; normal, 0.6–1.2)
Glucose, 320 mg/dL (normal, 70–110)
Serum albumin, 2.1 g/dL (normal, 4–6)
Hemoglobin (Hgb), 10.3 g/dL (13.5–17.5 g/dL male patients)
Hematocrit (Hct), 33% (normal, 39%–49% [male patients])
WBC count, 15,600/μL (normal, 4500–10,000/μL) with bands present
Platelets, 40,000/μL (normal, 130,000–400,000)
Prothrombin time (PT), 18 seconds (normal, 10–12)
Erythrocyte sedimentation rate (ESR), 65 mm/hour (normal, 0–20)
Procalcitonin, 1 μg/L (normal <0.25 μg/L)

Which of R.G.'s signs and symptoms are consistent with infection?

R.G. demonstrates numerous signs and symptoms consistent with infection. His WBC count (15,600/μL) is increased, and a “shift to the left” (presence of bands, ie, immature neutrophils) is observed on the differential. An increased WBC count is commonly observed with infection, particularly with bacterial pathogens. The WBC differential in patients with a bacterial infection often demonstrates a shift to the left associated with the acute bone marrow response to infection. Although infection is usually associated with an increased WBC, overwhelming sepsis can also be associated with a markedly decreased WBC count. In less-acute infection (eg, uncomplicated urinary tract infection, localized abscess), the WBC count may remain within the normal range because a less vigorous bone marrow response would be anticipated.

R.G.’s temperature is 104 °F (40 °C) by axillary measurement. Fever is a common manifestation of infection, with oral temperatures generally >100.40 °F (38 °C). Oral and axillary temperatures tend to be ~32.72 °F (0.4 °C) lower compared with rectal measurement. As a result, R.G.’s temperature would be expected to be 104.72 °F (40.4 °C) if his temperature had been taken rectally. In general, rectal measurement of temperature is a more reliable determination of fever. Some patients with overwhelming infection, however, may present with hypothermia with temperatures <96.80 °F (36 °C). Furthermore, patients with localized infections (eg, uncomplicated urinary tract infection, chronic abscesses) may be afebrile.

The bilateral lower lobe infiltrates on R.G.’s chest radiograph, the presence of copious amounts of yellow-green secretions from his endotracheal tube, and the erythema surrounding his central venous catheter are also compatible with one or more infectious processes. Furthermore, R.G. has signs and symptoms consistent with sepsis.

ESTABLISHING THE SEVERITY OF AN INFECTION

CASE 62-1, QUESTION 2: What signs and symptoms manifested by R.G. are consistent with a serious systemic infection?

The term *sepsis*, although a poorly defined syndrome, generally suggests more systemic infection with the presence of pathogenic microorganisms and/or their toxins in the blood. A uniform system for defining the spectrum of disorders associated with sepsis has been established, but it remains difficult to precisely define.[1]

The pathogenesis of sepsis is complex (**Fig. 62-1**) and only partially understood.[2,3] Gram-negative aerobes produce endotoxin that results in a cascade of endogenous mediator release, including tumor necrosis factor (TNF), interleukin 1 (IL-1) and interleukin 6 (IL-6), platelet-activating factor (PAF), and various other substances from mononuclear phagocytes and other cells. Although this initial stimulus commonly is associated with gram-negative endotoxin, other substances, including gram-positive exotoxin and fungal cell wall constituents, may also be associated with cytokine release. After release of TNF, IL-1, and PAF, arachidonic acid is metabolized to form leukotrienes, thromboxane A_2, and prostaglandins, particularly prostaglandin E_2 and prostaglandin I_2. IL-1 and IL-6 activate the T cells to produce interferon, IL-2, IL-4, and granulocyte–macrophage colony-stimulating factor. Increased endothelial permeability ensues. Subsequently, the endothelium releases two hemodynamically active substances: endothelium-derived relaxing factor (EDRF) and endothelin-l. Activation of the complement cascade (fragments C3a and C5a) follows, with additional vascular abnormalities and neutrophil activation. Other potentially important agents in this cascade include adhesion molecules, kinins, thrombin, myocardial depressant substance, endorphins, and heat shock protein. The net result of this cascade involves several hemodynamic, renal, acid–base, and other disorders. Uncontrolled inflammation and coagulation have a particularly important role in this sepsis cascade.[3]

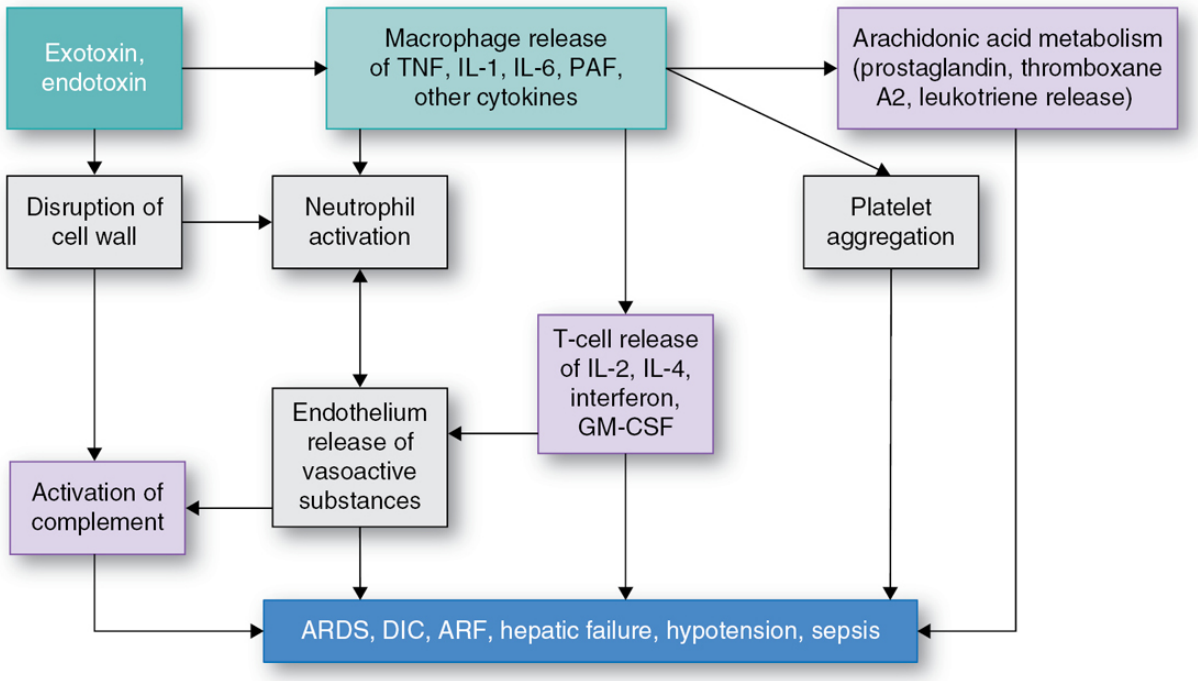

Figure 62-1 The sepsis cascade. ARDS, acute respiratory distress syndrome; ARF, acute renal failure; DIC, disseminated intravascular coagulation; GM-CSF, granulocyte–macrophage colony-stimulating factor; IL-1, interleukin-1; IL-2, interleukin-2; IL-4, interleukin-4; IL-6, interleukin-6; PAF, platelet-activating factor; TNF, tumor necrosis factor.

Hemodynamic Changes

Patients who are critically ill often have central intravenous (IV) lines in place for measuring cardiac output and systemic vascular resistance (SVR). These central lines are placed in the pulmonary artery resulting in a more precise measurement of critical hemodynamics. A normal SVR of 800 to 1200 dyne·s·cm^{-5} may fall to 500 to 600 dyne·s·cm^{-5} in septic shock because of extensive vasodilation. In response to vasodilation, the heart rate generally increases, resulting in increased cardiac output from a normal 4 to 6 L/minute to up to 11 to 12 L/minute in patients with sepsis; stroke volume remains unchanged or decreased. In addition to reflex tachycardia because of vasodilatation, stress-induced catecholamine

release (norepinephrine, epinephrine) also contributes to the rise in heart rate. The initial increase in cardiac output generally is insufficient to overcome the vasodilatory state, and hypotension ensues. In overwhelming septic shock, myocardial depression may result, resulting in a decreased cardiac output. The combination of decreased cardiac output and decreased SVR results in severe hypotension unresponsive to pressors and IV fluids. R.G. has hemodynamic evidence of septic shock. He is hypotensive (BP, 70/30 mm Hg) and tachycardic (HR, 130 beats/minute), presumably in response to vasodilation and catecholamine release.

Although vasodilation commonly occurs in sepsis, this dilation is unequal and chaotic. Some vascular beds constrict and others dilate, resulting in maldistribution of blood flow. In sepsis, blood generally is shunted away from the kidneys, mesentery, and extremities.

When sepsis has progressed to septic shock, blood flow to most major organs is decreased. Normal urine output of ~0.5 to 1.0 mL/kg/hour (30–70 mL/hour for a 154.32-pound [70 kg] patient) can decrease to <20 mL/hour in sepsis. The urine output for R.G. has decreased to 10 mL/hour, consistent with sepsis-induced perfusion abnormalities. Decreased blood flow to the kidney as well as mediator-induced microvascular failure can cause acute-tubular necrosis. R.G.'s uremia (BUN, 58 mg/dL) and increased serum creatinine concentration (3.8 mg/dL) are consistent with sepsis-induce decreased renal perfusion. Decreased blood flow to the liver may result in "shock liver," in which liver function tests, including alanine aminotransferase (ALT), aspartate aminotransferase (AST), and alkaline phosphatase, become elevated. The liver function tests for R.G. are not available; however, his serum albumin concentration is low (2.1 g/dL) and his PT of 18 seconds is prolonged. Decreased blood flow to the musculature classically is characterized by cool extremities, and decreased blood flow to the brain is often associated with decreased mentation. R.G. is confused, his extremities are cold, and the area around his mouth appears pale. All these signs and symptoms strongly suggest he is in septic shock.

Cellular Changes

The sepsis syndrome is associated with significant abnormalities in cellular metabolism. Glucose intolerance commonly is observed in sepsis, and patients with previously normal blood glucose levels may experience sudden increases in blood sugar. In some cases, a rise in glucose is one of the first signs of an infectious process. R.G.'s increased blood glucose concentration (320 mg/dL) is, therefore, consistent with infection. Other sensitive indicators of sepsis-associated inflammation include the ESR, C-reactive protein, and procalcitonin, nonspecific tests that are commonly elevated in various inflammatory states, including infection. The ESR, C-reactive protein, or procalcitonin can be used to follow the progression of infection; currently, R.G.'s ESR is elevated at 65 mm/hour. With appropriate management of infection, the ESR should decrease; inadequate treatment is associated with persistent elevation of the ESR and C-reactive protein. Procalcitonin is a more specific indicator for infection than ESR or C-reactive protein and has been used as a tool to discontinue antibiotics in patients with noninfectious inflammation.[4] At present, R.G.'s procalcitonin is 1.0 μg/L, which is consistent with infection-associated inflammation.

Respiratory Changes

Production of organic acids, such as lactate, increased glycolysis, decreased fractional extraction of oxygen, and abnormal delivery-dependent oxygen consumption are observed in sepsis.[3] This process leads to metabolic acidosis, with accompanying decreased serum bicarbonate levels. The lungs normally respond to metabolic acidosis in a compensatory manner with an increased respiratory rate (tachypnea), resulting in an increased elimination of arterial carbon dioxide. R.G.'s acid–base status is consistent with sepsis-associated metabolic acidosis (CO_2, 16 mEq/L) and compensatory respiratory alkalosis (respiratory rate, 24 breaths/minute).

A late complication of the above-mentioned sepsis cascade is acute respiratory distress syndrome (ARDS). ARDS initially was described as noncardiogenic pulmonary edema with severe hypoxemia caused by right-to-left intrapulmonary shunting resulting from atelectasis and edema-filled alveoli. The primary pathophysiology of ARDS is a breakdown in the natural integrity of the alveolar capillary network in the lung.[5] In the early phase of ARDS, patients have severe alveolar edema with large numbers of inflammatory cells, primarily neutrophils. The chronic phase of ARDS (10–14 days after the development of the syndrome) is associated with significant lung destruction. Emphysema, pulmonary vascular obliteration, and fibrosis commonly are observed. Severe ARDS is associated with ratios of arterial oxygen level to fraction of inspired oxygen (Pa_{O_2}/F_{IO_2}) of <100, low lung compliance, a need for high positive end-expiratory pressure (PEEP), and other respiratory maneuvers. At present, the treatment for this syndrome primarily is supportive, including mechanical ventilation, high-inspired oxygen, and PEEP. If patients fail to show improved gas exchange by day 7, the mortality associated with ARDS is high (>80%).[6] Although R.G. currently does not have ARDS, the severity of his sepsis strongly suggests that he may develop this complication.

Coagulation Changes

Disseminated intravascular coagulation (DIC) is a well-recognized sequel of sepsis because of bacterial and serious viral infections, including COVID-19 infections. Huge quantities of clotting factors and platelets are consumed in DIC as widespread coagulation and inflammation take place throughout the circulatory system.[3] As a result, the ratio of prothrombin time (PT) to international normalized ratio (INR) and the activated partial thromboplastin time (aPTT) are prolonged, and the platelet count commonly is decreased in sepsis. Decreased fibrinogen levels and increased fibrin split products generally are diagnostic for DIC. The PT of 18 seconds and the

decreased platelet count of 40,000/μL in R.G. are consistent with sepsis-induced DIC.[3]

Neurologic Changes

Central nervous system (CNS) changes, including lethargy, disorientation, confusion, and psychosis, are common in patients with sepsis. Altered mental status is also a well-recognized symptom associated with CNS infections, such as meningitis and brain abscess. These changes, however, are also commonly observed with other sites of infection. R.G.'s confused state is consistent with septic shock.[2–3]

PROBLEMS IN THE DIAGNOSIS OF AN INFECTION

Case 62-1, Question 3: R.G.'s medical history includes temporal arteritis and seizures chronically treated with corticosteroids and phenytoin. He recently received perioperative "stress doses" of hydrocortisone because of his surgical procedure. What medications or disease states confuse the diagnosis of infection?

Confabulating Variables

Various factors, including major surgery, acute myocardial infarction, and initiation of corticosteroid therapy, are associated with an increased WBC count. Unlike infection, however, a shift to the left does not occur with these disease states or drugs. In R.G., the stress dose of hydrocortisone and his recent surgical procedure might have contributed to the increased WBC count. The presence of bands in this patient, however, strongly suggests an acute bone marrow response to an infectious process.

Drug Effects

The ability of corticosteroids to mimic or mask infection is noteworthy. Corticosteroids are associated with an increased WBC count and glucose intolerance with the initiation of therapy or with increased doses. Furthermore, some patients experience corticosteroid-induced mental status changes that may mimic those associated with sepsis. Although corticosteroids mimic infection, their anti-inflammatory properties can also mask infection. For example, bowel perforation in a patient with ulcerative colitis would result in significant bacterial peritoneal contamination. Considering their potent anti-inflammatory effects, concomitant receipt of glucocorticoids may, however, reduce the classic findings of peritonitis. Furthermore, corticosteroids can reduce and sometimes ablate the febrile response. Thus, these corticosteroid-treated patients may be asymptomatic but are at great risk for gram-negative septic shock.

Another example of the influence of corticosteroids on the diagnosis of infection relates to neurosurgical procedures. Certain neurosurgical procedures are associated with significant trauma to the meninges, and steroids are often used to decrease the inflammation associated with this trauma. Dexamethasone, a corticosteroid commonly used to reduce the inflammation and swelling associated with neurosurgical procedures, is generally initiated at high doses. When the dexamethasone dose is decreased, such patients may subsequently experience classic meningismus, including stiff neck, photophobia, and headache. The lumbar puncture may demonstrate cloudy cerebrospinal fluid (CSF), an elevated WBC count, high CSF protein, and low CSF glucose. Although the signs and symptoms are consistent with infectious bacterial meningitis, if the CSF sample is sterile, this disease state represents an aseptic meningitis (ie, inflammation of the meninges without an infectious origin).[7] Certain drugs may cause aseptic meningitis, including nonsteroidal anti-inflammatory agents, sulfonamides, and certain antiepileptics.[8]

Fever

Fever is also a common finding with autoimmune diseases, such as systemic lupus erythematosus and temporal arteritis, or with sarcoidosis, chronic liver disease, and familial Mediterranean fever.[9],[10] Acute myocardial infarction, pulmonary embolism, postoperative pulmonary atelectasis, and certain cancers are also commonly associated with fever. Factitious fever or self-induced disease must be considered in certain patients. More recent evaluations of fever of unknown origin (FUO) have resulted in an inability to diagnose the ultimate etiology of the fever; in many instances, FUO results in the unnecessary use of antibiotics.[10] After infection, autoimmune disease, and malignancy have been ruled out, drug fever should be considered. Drugs, including certain antimicrobials and antiepileptics, have been associated with drug fever. Drug fever generally occurs after 7 to 10 days of therapy and resolves within 48 hours of drug discontinuation.[11] Some clinicians claim that patients with drug fever generally feel "well" and are unaware of their fever. A rechallenge with the offending agent usually results in the recurrence of fever. Drug fever should be considered a diagnosis of exclusion, however, and only after eliminating the presence of other disease states.

In summary, R.G. has an autoimmune disease, temporal arteritis, which is known to cause fever. Similarly, his corticosteroids (anti-inflammatory effects) and phenytoin (possible drug fever) use may confound the diagnosis of infection. His other signs and symptoms, however, strongly suggest an infectious origin of R.G.'s problems.

ESTABLISHING THE SITE OF THE INFECTION

Case 62-1, Question 4: What are the most likely sources of R.G.'s infection?

Independent of the presumed site of infection, drawing a series of blood samples may determine the presence of bacteremia in patients with sepsis. A thorough physical examination often documents the source of infection. Urosepsis, the most common cause of nosocomial infection, may be associated with dysuria, flank pain, and abnormal urinalysis.[12] Tachypnea, increased sputum production, altered chest radiograph, and hypoxemia may direct the clinician toward a pulmonary source. Evidence for an infected IV line might include pain, erythema, and purulent discharge around the IV catheter. Other potential sites of infection include the peritoneum, pelvis, bone, and CNS.

R.G. has several possible sites of infection. The copious production of yellow-green sputum, tachypnea, and the altered chest radiograph suggest the presence of pneumonia. The abdominal pain, absent bowel sounds, and recent surgical procedure, however, suggest an intra-abdominal source.[13] Further, the abnormal urinalysis (>50 WBC/HPF) and the erythema around the central venous catheter suggest urinary tract and intravenous catheter infections, respectively.

DETERMINING LIKELY PATHOGENS

CASE 62-1, QUESTION 5: What are the most likely pathogens associated with R.G.'s infection(s)?

R.G. has several possible sources of infection and likely pathogens. **Table 62-1** provides a classification of infectious organisms (eg, gram-positive, gram-negative, aerobic, and anaerobic), and **Table 62-2** lists the most likely organisms associated with sites of infection. Bacterial pneumonia is caused by various pathogens, including *Streptococcus pneumoniae*, *Enterobacteriaceae*, and "atypical" pathogens (eg, *Legionella pneumophila*).[14] However, empirical antimicrobial therapy directed

against all the above organisms is not necessary in all patients. Bacterial community-acquired pneumonia in normal hosts is generally associated with *S. pneumoniae*, *Haemophilus influenzae*, and "atypical" bacterial pathogens.[15] However, viral etiology, including pneumonia because of COVID-19, should always be considered. In contrast to community-acquired, nosocomial (acquired in hospital or in other health care facilities, eg, nursing home) pneumonia is frequently associated with gram-negative bacilli (eg, *Escherichia coli*, *Klebsiella* species, *Enterobacter* species, and *Pseudomonas aeruginosa*) and *Staphylococcus aureus*. If the pneumonia is the result of a gastric aspiration, empirical antibacterial treatment of mouth anaerobes generally takes place; however, their true pathogenicity in aspiration pneumonia is not clear. For the empirical treatment of hospital-associated pneumonia or ventilator-associated pneumonia, knowledge of a hospital epidemiology is useful. If *P. aeruginosa* or *Enterobacter cloacae* predominate in an institution, then broad-spectrum agents should be used directed against these pathogens. Similarly, prior or concurrent receipt of antimicrobial therapy significantly impacts the choice of empirical therapy. Age is an important determinant in the epidemiology of infection. For example, meningitis in a neonate is commonly caused by group B streptococci, *E. coli*, and *Listeria monocytogenes*, whereas these bacteria are uncommon pathogens in normal healthy adults. The presence of concomitant diseases, such as chronic obstructive pulmonary disease (COPD) or alcohol and IV drug abuse, also increases the likelihood for infection because of certain pathogens. As an example, patients with COPD-associated community-acquired pneumonia more likely are infected by *S. pneumoniae* and *H. influenzae*, whereas chronic alcoholics more likely have *Klebsiella* species as a source of pneumonia.

Table 62-1
Classification of Infectious Organisms

1. BACTERIA
   Aerobic
   Gram-positive

Cocci
Streptococci: pneumococcus, viridans streptococci; group A streptococci
Enterococcus
Staphylococci: *Staphylococcus aureus, Staphylococcus epidermidis*
Rods (bacilli)
Corynebacterium
Listeria
Gram negative
Cocci
Moraxella
Neisseria (Neisseria meningitidis, Neisseria gonorrhoeae)
Rods (bacilli)
Enterobacteriaceae (*Escherichia coli, Klebsiella, Enterobacter, Citrobacter, Proteus, Serratia, Salmonella, Shigella, Morganella, Providencia*)
Campylobacter
Pseudomonas
Helicobacter
Haemophilus (coccobacilli morphology)
Legionella
Anaerobic
Gram-positive
Cocci
Peptococcus
Peptostreptococcus
Rods (bacilli)
Clostridia (*Clostridium perfringens, Clostridium tetani, Clostridioides difficile*)
Propionibacterium acnes
Gram negative
Cocci
None
Rods (bacilli)
Bacteroides (*Bacteroides fragilis, Bacteroides melaninogenicus*)
Fusobacterium
Prevotella

2. FUNGI
   Aspergillus, Candida, Coccidioides, Cryptococcus, Histoplasma, Mucor, Tinea, Trichophyton
3. VIRUSES
   Influenza; hepatitis A, B, C, D, E; human immunodeficiency virus (HIV); rubella; herpes; influenza; cytomegalovirus; respiratory syncytial virus; Epstein–Barr virus; severe acute respiratory syndrome (SARS) virus, COVID-19
4. CHLAMYDIAE
   Chlamydia trachomatis

Chlamydia psittaci
Chlamydophila pneumoniae
Lymphogranuloma venereum (LGV)

5. RICKETTSIAE
   Rocky Mountain spotted fever, Q fever
   Ureaplasma
6. MYCOPLASMAS
   Mycoplasma pneumoniae, Mycoplasma hominis
7. SPIROCHETES
   Treponema pallidum, Borrelia burgdorferi (Lyme disease)
8. MYCOBACTERIA
   Mycobacterium tuberculosis
   Mycobacterium avium intracellulare

Table 62-2
Site of Infection: Suspected Organisms

Site/Type of Infection	Suspected Organisms
1. Respiratory	
Pharyngitis	Viral, group A streptococci
Otitis	Viral, *Haemophilus influenzae, Streptococcus pneumoniae, Moraxella catarrhalis*
Acute sinusitis	Viral, *S. pneumoniae, H. influenzae, M. catarrhalis*
Chronic sinusitis	Anaerobes, *Staphylococcus aureus* (as well as suspected organisms associated with acute sinusitis)
Epiglottitis	Viral, *H. influenza*
Pneumonia	
Community-acquired	
Normal host	*S. pneumoniae*, viral, mycoplasma
Aspiration	Normal aerobic and anaerobic mouth flora
Pediatrics	*S. pneumoniae, H. influenzae*
COPD	*S. pneumoniae, H. influenzae, Legionella, Chlamydia, Mycoplasma*
Alcoholic	*S. pneumoniae, Klebsiella*
Hospital-	

acquired	
Aspiration	Mouth anaerobes, aerobic gram-negative rods, *S. aureus*
Neutropenic	Molds, aerobic gram-negative rods, *S. aureus*
HIV	Molds, *Pneumocystis, Legionella, Nocardia, S. pneumoniae, Pseudomonas*
2. Urinary Tract	
Community-acquired	*Escherichia coli*, other gram-negative rods, *S. aureus, Staphylococcus epidermidis*, enterococci
Hospital-acquired	Resistant aerobic gram-negative rods, enterococci
3. Skin and Soft Tissue	
Cellulitis	Group A streptococci, *S. aureus*
IV catheter infection	*S. aureus, S. epidermidis*
Surgical wound	*S. aureus*, gram-negative rods
Diabetic ulcer	*S. aureus*, gram-negative aerobic rods, anaerobes
Furuncle	*S. aureus*
4. Intra-abdominal	*Bacteroides fragilis, E. coli*, other aerobic gram-negative rods, enterococci
5. Gastroenteritis	*Salmonella, Shigella, Helicobacter, Campylobacter, Clostridioides difficile*, enterotoxigenic-hemorrhagic *E. coli, Giardia*, amoeba, viral
6. Endocarditis	
Preexisting valvular disease	*Viridans streptococci*
IV drug user	*S. aureus*, aerobic gram-negative rods, enterococci, fungi
Prosthetic valve	*S. epidermidis, S. aureus*
7. Osteomyelitis and Septic Arthritis	*S. aureus*, aerobic gram-negative rods
8. Meningitis	
<2 months	*E. coli*, group B streptococci, *Listeria*
2 months–12 years	*S. pneumoniae, Neisseria meningitidis, H. influenzae*

Adults	*S. pneumoniae, N. meningitidis*
Hospital-acquired	*S. pneumoniae, N. meningitidis*, aerobic gram-negative rods
Post-neurosurgery	*S. aureus*, aerobic gram-negative rods

COPD, chronic obstructive pulmonary disease; IV, intravenous.

Immune status is an important predictor for certain pathogens. Patients with human immunodeficiency virus (HIV) infection/AIDS or those receiving Atgam, cyclosporine (or tacrolimus), sirolimus, and corticosteroids have quantitative and/or qualitative lymphocyte deficiency and are at risk for infections because of cytomegalovirus, *Pneumocystis jirovecii*, atypical mycobacteria, and *Cryptococcus neoformans.* Patients with leukemia and neutropenia are at risk for infection caused by aerobic gram-negative bacilli, including *P. aeruginosa*, *Candida* species, and *Aspergillus* species, as well as the above-mentioned pathogens.

In 2019, several cluster cases of viral pneumonia were reported from Wuhan City, China. Cases continued to emerge rapidly, increasing to 282 confirmed cases within 10 days with 51 patients who are severely ill, 12 patients in critical condition, and 6 deaths.[16] The pathogen responsible for the severe respiratory syndrome known as COVID-19 (coronavirus disease 2019) was later identified as a novel coronavirus, SARs-CoV-2 (severe acute respiratory syndrome coronavirus 2). The virus spread throughout the world in the ensuing months, requiring massive quarantine and leading to economic shutdown and social unrest unseen in recent history.[17] COVID-19 is associated with a wide range of severity of the disease. Although the majority of patients infected with COVID-19 have mild symptoms or are asymptomatic, many patients require hospitalization including ICU care and mechanical intubation. Patients at risk for more severe disease include those with advanced age, cancer, chronic kidney disease, COPD, other immunocompromised states, obesity, serious heart conditions, sickle cell disease, and diabetes mellitus.[18] Commonly observed symptoms

include fever/chills, cough, shortness of breath, fatigue, muscle aches, headache, loss of taste or smell, sore throat, congestion, nausea, vomiting, and diarrhea. These symptoms can appear 2 to 14 days after initial exposure to the virus.[19]

In R.G., the abdomen, respiratory tract, urinary tract, and IV catheter are all potential sites of infection. Intra-abdominal infection is likely caused by aerobic gram-negative enteric bacteria, *Bacteroides fragilis*, and possibly enterococcus; nosocomial urinary tract infection is usually caused by aerobic gram-negative bacteria. R.G.'s pneumonia could be because of gram-negative bacilli and staphylococci, as well as other organisms including SARS-CoV-2. Furthermore, his long-term use of corticosteroids may predispose him to infection caused by more opportunistic organisms, including *Legionella*, *P. jirovecii*, and certain fungi. Lastly, his IV catheter infection suggests infection caused by staphylococci, including *Staphylococcus epidermidis* and *Staphylococcus aureus.*

MICROBIOLOGIC TESTS AND SUSCEPTIBILITY OF ORGANISMS

Case 62-1, Question 6: A Gram stain of R.G.'s tracheal aspirate shows gram-negative bacilli. What tests may assist with the identification of the pathogen(s)?

Once the site of infection has been determined and host defense and other epidemiologic factors have been evaluated, additional tests can be performed to identify the pathogen. The Gram stain uses crystal violet solution and iodine staining bacteria gram positive or gram negative; some organisms are gram variable. In addition, the shape of the organism (cocci, bacilli) is readily apparent with the use of the Gram stain. Streptococci and staphylococci are gram-positive cocci, whereas *E. coli*, *E. cloacae*, and *P. aeruginosa* appear as gram-negative bacilli (see Table 62-1).[20] If the Gram stain of the tracheal aspirate demonstrates gram-positive cocci in clusters,

empirical antistaphylococcal therapy is indicated. In contrast, if the Gram stain shows gram-negative rods, antimicrobials with activity against these pathogens should be used.

Similar to the Gram stain in bacterial infection, the India ink and potassium hydroxide stains are helpful in the identification of certain fungi. The acid-fast bacilli stain is critical in the diagnosis of infection caused by *Mycobacterium tuberculosis* or atypical mycobacteria.

In R.G.'s case, the Gram stain suggests that antimicrobials active against gram-negative bacilli should be used. **Table 62-3** provides a classification of antibacterials (eg, different generations of cephalosporins). **Tables 62-4**, **62-5**, and **62-6** list in vitro susceptibilities of aerobic gram-positive, gram-negative, and anaerobic bacteria, respectively.

Table 62-3
Classification of Antibacterials

a-Lactam Antibiotics
***b**-Lactam and **b**-Lactamase Inhibitors Combinations*
Amoxicillin plus clavulanic acid (Augmentin)
Ampicillin plus sulbactam (Unasyn)
Ceftazidime plus avibactam (Avycaz®)
Ceftolozane plus tazobactam (Zerbaxa)
Imipenem/cilastatin plus relebactam (Recarbrio™)
Meropenem plus vaborbactam (Vabomere)
Piperacillin plus tazobactam (Zosyn)
Ticarcillin plus clavulanic acid (Timentin)[a]
Carbacephem
Loracarbef (Lorabid)[a]
Carbapenems
Doripenem (Doribax®)
Ertapenem (Invanz)
Imipenem/cilastatin (Primaxin)
Meropenem (Merrem)
Cephalosporins
First Generation
Cefadroxil (Duricef)
Cefazolin (Ancef)
Cephalexin (Keflex)
Second Generation

Cefaclor (Ceclor)
Cefamandole (Mandol®)[a]
Cefonicid (Monocid)
Ceforanide (Precef)
Cefotetan (Cefotan®)
Cefoxitin (Mefoxin)
Cefprozil (Cefzil)
Cefuroxime (Zinacef)
Cefuroxime axetil (Ceftin)
Third Generation
Cefdinir (Omnicef)
Cefditoren (Spectracef)
Cefixime (Suprax)
Cefotaxime (Claforan)
Cefpodoxime proxetil (Vantin)
Ceftazidime (Fortaz)
Ceftibuten (Cedax)
Ceftizoxime (Cefizox®)
Ceftriaxone (Rocephin)
Fourth Generation
Cefepime (Maxipime)
Fifth Generation
Ceftaroline (Teflaro™)
Siderophore Cephalosporins
Cefiderocol (Fetroja®)
Penicillins
Natural Penicillins
Penicillin G
Penicillin V
Aminopenicillins
Ampicillin (Omnipen)
Amoxicillin (Amoxil)
Bacampicillin (Spectrobid)[a]
Penicillinase-Resistant Penicillins
Isoxazolyl penicillins (dicloxacillin, oxacillin, cloxacillin)
Nafcillin (Unipen)
Monobactams
Aztreonam (Azactam)

Non–a-Lactam Antibiotics

Aminoglycosides
Amikacin (Amikin)
Gentamicin (Garamycin)
Neomycin (Mycifradin)
Netilmicin (Netromycin)[a]

Plazomicin (Zemdri®)
Streptomycin
Tobramycin (Nebcin)
Folate inhibitors
Sulfadiazine
Sulfadoxine (Fansidar)
Trimethoprim (Trimpex)
Trimethoprim-sulfamethoxazole (Bactrim, Septra)
Glycopeptides
Dalbavancin (Dalvance)
Oritavancin (Orbactiv®)
Telavancin (Vibativ®)
Vancomycin (Vancocin)
Lincosamides
Clindamycin (Cleocin)
Macrolides
Azithromycin (Zithromax)
Clarithromycin (Biaxin®)
Dirithromycin (Dynabac®)[a]
Erythromycin (Erythrocin)
Fidaxomicin (Dificid)
Ketolides
Telithromycin (Ketek)[a]
Oxazolidinones
Linezolid (Zyvox)
Tedizolid (Sivestro®)
Pleuromutilins
Lefamulin (Xenleta®)
Quinolones
Ciprofloxacin (Cipro)
Delafloxacin (Baxdela®)
Gemifloxacin (Factive)
Levofloxacin (Levaquin)
Moxifloxacin (Avelox)
Norfloxacin (Noroxin®)
Ofloxacin (Floxin)
Tetracyclines
Doxycycline (Vibramycin)
Eravacycline (Xerava)
Minocycline (Minocin)
Omadacycline (Nuzyra®)
Tetracycline (Sumycin)
Tigecycline (Tygacil)
Others

Chloramphenicol (Chloromycetin)
Dalfopristin/Quinupristin (Synercid)
Daptomycin (Cubicin®)
Metronidazole (Flagyl)

[a]Not on the U.S. market.

MR, methicillin-resistant; TGC, third-generation cephalosporin.

[a]Nonpneumococcal streptococci.

[b]Usually requires combination therapy (eg, ampicillin plus gentamicin or ampicillin plus ceftriaxone) for endocarditis.

[c]Levofloxacin (eg, gemifloxacin, moxifloxacin) is more active than ciprofloxacin against staphylococci and streptococci.

[d]Active versus vancomycin-resistant *E. faecium*.

[e]Active against *Enterococcus faecium* but unpredictable against *E. faecalis.*

[f]Cefotaxime, ceftizoxime, ceftriaxone, and cefoperazone. Ceftazidime has comparatively inferior antistaphylococcal and antipneumococcal activity compared to cefotaxime or ceftriaxone. Cefotaxime, ceftriaxone, and cefepime are the most reliable cephalosporins versus *Streptococcus pneumoniae*.

Culture and Susceptibility Testing

Culture and susceptibility testing provides final identification of the pathogen, as well as information regarding the likely effectiveness of various antimicrobials. Although these tests further clarify the pathogen, they generally require 18 to 24 hours to complete. Once the pathogen has been identified, the most effective agents (**Table 62-7**) and institution-specific susceptibility data allow for the selection of the most appropriate antimicrobial.

Table 62-7
Antimicrobials of Choice in the Treatment of Bacterial Infection

Organism	Drug of Choice	Alternatives	Comments
Aerobes			
Gram-Positive Cocci			
Streptococcus pyogenes (group A streptococci)	Penicillin	Clindamycin, macrolide, cephalosporin	Clindamycin is the most reliable alternative for patients who are allergic to penicillin.
Streptococcus pneumoniae	Ceftriaxone, ampicillin, oral amoxicillin	Macrolide, cephalosporin, doxycycline	Although the incidence of penicillin–*non*-susceptible pneumococci is 20%–30%, high-dose penicillin or amoxicillin is active against most of these isolates.
			Penicillin-resistant pneumococci commonly demonstrate resistance to other agents, including erythromycin, tetracyclines, and cephalosporins.
			Anti-pneumococcal quinolones (gemifloxacin, levofloxacin, moxifloxacin), ceftriaxone, and cefotaxime are options for treatment of high-level penicillin-resistant isolates.
Enterococcus faecalis	Ampicillin with or without gentamicin Ampicillin with or without ceftriaxone	Piperacillin-tazobactam; vancomycin with or without gentamicin; daptomycin, linezolid, tedizolid, tigecycline	Most commonly isolated enterococcus (80%–85%). Most reliable anti-enterococcal agents are ampicillin (penicillin, piperacillin-tazobactam), vancomycin, and linezolid. Monotherapy generally inhibits but does not kill the enterococcus. Daptomycin is unique in its bactericidal activity against enterococci. Aminoglycosides or ceftriaxone must be added to ampicillin to provide bactericidal activity. High-level aminoglycoside resistance should be determined for endocarditis.
Enterococcus faecium	Vancomycin with or without gentamicin	Linezolid, tedizolid, daptomycin, dalfopristin/quinupristin (D/Q), oritavancin, tigecycline	Second most common enterococcal organism (10%–20%) and is more likely than *E. faecalis* to be resistant to multiple antimicrobials. Most reliable agents are daptomycin, D/Q, oritavancin, and linezolid. Monotherapy generally inhibits but does not kill the enterococcus. Aminoglycosides or ceftriaxone must be added to cell wall–active agents to provide bactericidal activity. Ampicillin and vancomycin resistance is common. Daptomycin, D/Q, and linezolid are drugs of choice for vancomycin-resistant isolates.

Organism	Drug of Choice	Alternatives	Comments
Staphylococcus aureus methicillin-resistant	Nafcillin, oxacillin, dicloxacillin, cefazolin	Vancomycin, clindamycin, dalbavancin, linezolid, oritavancin	Isolates of 80%–85% are resistant to penicillin. Most isolates are susceptible to nafcillin, cephalosporins, trimethoprim-sulfamethoxazole, and clindamycin. First-generation cephalosporins are equal to nafcillin. Most second- and third-generation cephalosporins are adequate in the treatment of infection (exceptions include ceftazidime and cefonicid). Methicillin-resistant *S. aureus* must be treated with vancomycin or alternatives (eg, linezolid, daptomycin, delafloxacin, ceftaroline, D/Q, the vancins); trimethoprim-sulfamethoxazole, doxycycline, or minocycline can be used for community-acquired MRSA.
	Vancomycin	Trimethoprim-sulfamethoxazole, minocycline, doxycycline, daptomycin, tigecycline, telavancin, oritavancin, dalbavancin, ceftaroline, delafloxacin	
Staphylococcus epidermidis methicillin-resistant	Nafcillin, oxacillin	Cefazolin, vancomycin, clindamycin	Most isolates are resistant *to* β-lactam, clindamycin, and trimethoprim–sulfamethoxazole. Most reliable agents are vancomycin, daptomycin, D/Q, and linezolid. Rifampin is active and can be used in conjunction with other agents; however, monotherapy with rifampin is associated with the development of resistance.
	Vancomycin	Daptomycin, linezolid, D/Q	
Gram-Positive Bacilli			
Diphtheroids	Penicillin	Cephalosporin	
Corynebacterium jeikeium	Vancomycin	Erythromycin, quinolone	
Listeria monocytogenes	Ampicillin (with or without gentamicin)	Trimethoprim-sulfamethoxazole	
Gram-Negative Cocci			
Moraxella catarrhalis	Trimethoprim-sulfamethoxazole	Amoxicillin-clavulanic acid, erythromycin, doxycycline, second- or third-generation cephalosporin	
Neisseria gonorrhoeae	Ceftriaxone		
Neisseria meningitidis	Penicillin	Third-generation cephalosporin	
Gram-Negative Bacilli			
Campylobacter fetus	Imipenem/cilastatin	Gentamicin	
Campylobacter jejuni	Azithromycin	Tetracycline, amoxicillin-clavulanic acid, quinolone	
Enterobacter	Carbapenem	Quinolone, aminoglycoside	Not predictably inhibited by third-generation cephalosporins. Carbapenems, quinolones, trimethoprim-sulfamethoxazole, cefepime, and aminoglycosides are most active agents.
Escherichia coli	Third-generation cephalosporin	First- or second-generation cephalosporin, gentamicin	ESBL producers should be treated with a carbapenem/β-lactamase combination, later-generation cephalosporin/β-lactamase combinations (ie, ceftolozane–tazobactam, ceftazidime-avibactam), plazomicin, eravacycline, or cefiderocol
Haemophilus influenzae	Third-generation cephalosporin	β-Lactamase inhibitor combinations, second-generation cephalosporin, trimethoprim-sulfamethoxazole	
Helicobacter pylori	PPI + clarithromycin + amoxicillin *or* metronidazole	PPI + bismuth subsalicylate + tetracycline + nitroimidazole	
Klebsiella pneumoniae	Third-generation cephalosporin	First- or second-generation cephalosporin, gentamicin, trimethoprim-sulfamethoxazole	ESBL producers should be treated with a carbapenem β-lactamase combination, later-generation cephalosporin/β-lactamase combinations (ie, ceftolozane-tazobactam, ceftazidime-avibactam), plazomicin, eravacycline, or cefiderocol

Organism	Drug of Choice	Alternatives	Comments
Legionella	Fluoroquinolone	Macrolide with or without rifampin, doxycycline	
Proteus mirabilis	Ampicillin	First-generation cephalosporin, trimethoprim-sulfamethoxazole	
Other *Proteus*	Third-generation cephalosporin	β-Lactamase inhibitor combination, aminoglycoside, trimethoprim-sulfamethoxazole	
Pseudomonas aeruginosa	Antipseudomonal penicillin or antipseudomonal cephalosporin with or without aminoglycoside (or quinolone)	Quinolone or imipenem with or without aminoglycoside	Most active agents include aminoglycosides, doripenem, imipenem, meropenem, ceftazidime, ceftazidime-avibactam, cefepime, ceftolozane-tazobactam, aztreonam, imipenem-relebactam, and the extended-spectrum penicillins. Monotherapy is adequate for most pseudomonal infections.
Salmonella typhi	Quinolone	Ceftriaxone	
Serratia marcescens	Third-generation cephalosporin	Trimethoprim-sulfamethoxazole, aminoglycoside, carbapenem	
Shigella	Quinolone	Trimethoprim-sulfamethoxazole, ampicillin	
Stenotrophomonas maltophilia	Trimethoprim-sulfamethoxazole	Ceftazidime, minocycline, β-lactamase inhibitor combination (Timentin)	
Anaerobes			
Bacteroides fragilis	Metronidazole	β-Lactamase inhibitor combinations, carbapenems	Most active agents (95%–100%) include metronidazole, the β-lactamase inhibitor combinations ampicillin-sulbactam, piperacillin-tazobactam, ticarcillin-clavulanic acid, and carbapenems. Clindamycin, cefoxitin, cefotetan, cefmetazole, ceftizoxime have good activity but not to the degree of metronidazole.
Clostridioides difficile	Vancomycin, fidaxomicin		Fidaxomicin is superior to other agents in the prevention of relapse.
Fusobacterium	Penicillin	Metronidazole, clindamycin	
Other Oropharyngeal			
Prevotella	β-Lactamase inhibitor combination	Metronidazole, clindamycin	
Peptostreptococcus	Penicillin	Clindamycin, cephalosporin	Most β-lactams active (exceptions include aztreonam, nafcillin, ceftazidime)
Other			
Actinomyces israelii	Penicillin	Tetracyclines	
Nocardia	Trimethoprim-sulfamethoxazole	Amikacin, minocycline, imipenem	
Chlamydia trachomatis	Doxycycline	Azithromycin	
Chlamydophila pneumoniae	Doxycycline	Azithromycin, clarithromycin	
Mycoplasma pneumoniae	Doxycycline	Azithromycin, clarithromycin	
Borrelia burgdorferi	Doxycycline	Ampicillin, second- or third-generation cephalosporin	
Treponema pallidum	Penicillin	Doxycycline	

ESBL, extended-spectrum β-lactamase.

DISK DIFFUSION

The most widely used tests for bacterial susceptibility are the disk diffusion and the broth dilution methods. The disk diffusion (Kirby–Bauer) technique uses an agar plate on which an inoculum of the organism is placed. After inoculation, several antimicrobial-laden disks are placed on the plate, and evidence of bacterial growth is observed after 18 to 24 hours. If the antimicrobial is active against the pathogen, a zone of growth inhibition around the disk is observed. Based on the guidelines provided by the Clinical and Laboratory Standards Institute (CLSI), the diameter of inhibition is reported as susceptible, intermediate, or resistant. CLSI zones of inhibitions are determined considering known achievable antimicrobial concentrations in vivo. However, broth dilution (see below) minimum inhibitory concentration (MIC) allows for a better comparison with achievable antimicrobial concentrations.

BROTH DILUTION

The broth dilution method introduces a bacterial inoculum into several tubes or wells filled with broth. Serial dilutions of antimicrobials (eg, nafcillin 0.5, 1.0, and 2.0 µg/mL) are placed in the respective wells. After bacterial incubation for 18 to 24 hours, the wells are examined for bacterial growth. If the well is cloudy, bacterial growth has occurred, suggesting resistance to the specific antimicrobial at that concentration. As an example, if bacterial growth is observed with *S. aureus* at 0.5 µg/mL of nafcillin but not at 1.0 µg/mL, then 1.0 µg/mL would be considered the MIC for nafcillin against *S. aureus.*

Similar to the disk diffusion method, the CLSI provides guidelines[21] that also take into account antimicrobial pharmacokinetics to determine whether the MIC should be reported as susceptible, intermediately susceptible, or resistant. MIC interpretations are both pathogen- and antimicrobial-specific. For example, ciprofloxacin achieves serum concentrations of only 1 to 4 µg/mL, whereas the fourth-generation cephalosporin, cefepime, achieves peak serum concentrations of 75 to 100 µg/mL; consequently, an MIC of 4.0

μg/mL for *P. aeruginosa* would be interpreted by CLSI as resistant to ciprofloxacin but susceptible to cefepime.

Although these tests provide an accurate assessment of in vitro susceptibility, the time delay (18–24 hours) can hinder streamlining of therapy. An alternative efficient, but more expensive, MIC test is the E test, which uses an antibiotic-laden plastic strip with increasing concentrations of a specific antimicrobial from one end to the other. The strip is placed on an agar plate with the actively growing pathogen. Inhibition of growth observed at specific marks on the strip coincides with the MIC of the organism. Numerous studies have confirmed that the E test is as effective as traditional susceptibility testing. Several automated antimicrobial susceptibility systems are available in the United States, including Phoenix (Becton Dickinson, Franklin Lakes, NJ), Vitek (bioMérieux, Durham, NC), MicroScan WalkAway (Siemens Healthcare Diagnostics, Tarrytown, NY), and Sensititre (Trek Diagnostics, Cleveland, OH). These systems generally use a computerized algorithm for interpreting results and determine the antibiotic MIC for the organism by using specialized decision technology. Two major advantages of automated susceptibility methodologies include a reduction in labor and faster reporting of susceptibility results, potentially leading to the earlier initiation of appropriate antibiotic therapy. Although these represent advantages, disadvantages exist, particularly with cystic fibrosis isolates. Most clinical microbiology laboratories use automated susceptibility testing systems. Although these automated antimicrobial susceptibility systems are an improvement over traditional broth dilution and disc diffusion methods, other emerging technologies including polymerase chain reaction (PCR) and other “next-generation” systems are likely to result in more rapid identification of pathogens and their associated antimicrobial susceptibility. In the context of COVID-19, the most reliable method of identification and diagnosis is a viral PCR of antigen or nucleic acid via respiratory sample (ie, nasal or oral swabs or saliva) to determine if a patient is infected with SARS-CoV-2.[22]

Although susceptibility testing is relatively well standardized for aerobic gram-negative and gram-positive organisms, its utility is not

as established for anaerobes[23] and fungi.[24] In general, despite improvements in the standardization of testing in anaerobes, institutions do not routinely perform susceptibility testing for these bacteria. In contrast, susceptibility testing is available for *Candida* species, and these in vitro data have demonstrated to predict clinical success in the patient care setting.

The consensus of the CLSI and other experts is that anaerobic isolates from blood, bone and joint sources, brain abscesses, empyemic fluid, and other body fluids that are normally sterile should be considered for susceptibility testing. However, in general, these susceptibilities are rarely performed.[23] Progress has been made in developing a standardized test for determining fungal susceptibility, but the emphasis has been on the susceptibility of *Candida* species to azoles in the treatment of candidiasis.[24] Although CLSI and other organizations have established standardized susceptibility testing for molds, the correlation with clinical outcome is variable. The best correlation between antifungal susceptibility testing and efficacy lies with the use of azoles in the treatment of disseminated aspergillosis.[25]

DETERMINATION OF ISOLATE PATHOGENICITY

CASE 62-1, QUESTION 7: *Serratia marcescens* grows from a culture of R.G.'s endotracheal aspirate. How can it be determined whether an isolate represents a true bacterial infection versus colonization or contamination?

A positive culture may represent colonization, contamination, or infection. Colonization indicates that bacteria are present at the site; however, they are not actively causing infection. If the bacterium is determined to be a colonizer, antibacterials are not indicated. Poor sampling techniques or inappropriate handling of specimens can result in contamination. Contamination differs from colonization in

that these isolates are not truly at the site in question and were inadvertently introduced with the handling of the specimen. The *S. marcescens* growing from R.G. could represent infection, colonization, or contamination. If a suction catheter was used to sample R.G.'s endotracheal aspirate, the infecting organism likely would be cultured; however, other nonpathogenic flora would also appear in the culture medium (colonization). Furthermore, if the sample is not handled aseptically by the clinician or the microbiology laboratory, bacterial contamination is possible.

In summary, culture results do not solely identify true pathogens. In R.G., the *Serratia* may be a pathogen, contaminant, or colonizer. Nevertheless, considering the severity of R.G.'s illness and his associated respiratory symptoms, treatment directed against this pathogen is necessary.

ANTIMICROBIAL TOXICITIES

CASE 62-1, QUESTION 8: Considering the positive culture for *Serratia*, his increased respiratory secretions, and a worsening chest radiograph, ventilator-associated pneumonia is likely present. Pending antibacterial susceptibility results, R.G. is supposed to receive an empiric regimen of imipenem-cilastatin and gentamicin. A review of his medical records indicates that R.G. has no known allergies. Are there equally effective, less toxic options for this patient?

Adverse Effects and Toxicities

Before starting antimicrobial therapy, it is important to elicit an accurate drug and allergy history. When the patient has reported "allergy," it is necessary to determine whether the reaction was intolerance, toxicity, or true allergy. For example, gastric intolerance caused by oral doxycycline is common; however, this adverse effect does not represent an allergic manifestation. Although R.G. has no known allergies, neither imipenem nor gentamicin are optimal choices. Imipenem-cilastatin is associated with seizures, particularly

in patients with renal failure and in doses in excess of 50 mg/kg/day. Considering R.G.'s acute onset of renal failure and his history of seizures, other carbapenems, such as meropenem or doripenem, or alternative classes of antibacterials would be preferable. Gentamicin similarly may not be a good choice for R.G. His increased age and declining renal function predispose him to aminoglycoside nephrotoxicity and ototoxicity (cochlear and vestibular).[26] A reasonable recommendation pending susceptibility results would be to discontinue imipenem and gentamicin and treat with meropenem or doripenem with or without a fluoroquinolone. **Table 62-8** lists common antimicrobial adverse effects and toxicities.

Table 62-8
Antimicrobial Adverse Effects and Toxicities

Antibiotics	Side Effects	Comments
β-Lactams (penicillin, cephalosporins, monobactams, carbapenems)	*Allergic:* anaphylaxis, urticaria, serum sickness, rash, fever	Many patients will have "ampicillin rash" or "β-lactam rash" with no cross-reactivity with any other penicillins/β-lactams. Classically maculopapular rash and most commonly observed in patients with concomitant EBV disease. Likelihood of IgE-mediated cross-reactivity between penicillins and cephalosporins <5% (first and second generation) and <3% (third and fourth generation). Most recent data strongly suggest minimal IgE cross-reactivity between penicillins and imipenem/meropenem. No IgE cross-reactivity between aztreonam and penicillins.

Antibiotics	Side Effects	Comments
	Diarrhea	Particularly common with ampicillin, Augmentin, ceftriaxone. Antibiotic-associated colitis can occur with most antimicrobials.
	Hematologic: anemia, thrombocytopenia, antiplatelet activity, hypoprothrombinemia	Hemolytic anemia more common with higher doses. Antiplatelet activity (inhibition of platelet aggregation) most common with the antipseudomonal penicillins and high serum levels of other β-lactams. hypoprothrombinemia more often associated with those cephalosporins with the methyl-tetrazole-thiol side chain (cefamandole, cefotetan). Reaction preventable and reversible with vitamin K
	Hepatitis or biliary sludging	Hepatitis most common with oxacillin. Biliary sludging and stones reported with ceftriaxone
	Phlebitis	
	Seizure activity	Associated with high levels of β-lactams, particularly penicillins and imipenem
	Potassium load	Penicillin G (K^+)
	Sodium load	Piperacillin-tazobactam
	Nephritis	Interstitial nephritis reported for most β-lactams
	Neutropenia	Nafcillin
	Disulfiram reaction	Associated with cephalosporins with methyl-tetrazole-thiol side chain (cefamandole, cefotetan)

Antibiotics	Side Effects	Comments
	Hypotension, nausea	Associated with rapid infusion of imipenem
Aminoglycosides (gentamicin, tobramycin, amikacin, netilmicin)	Nephrotoxicity	Incidence 10%–15%. Generally reversible, usually occurs after 5–7 days of therapy. *Risk factors:* dehydration, age, dose, duration, concurrent nephrotoxins, renal disease
	Ototoxicity	Incidence 1%–5%, often irreversible. Both cochlear and vestibular toxicity occur
	Neuromuscular paralysis	Rare, most common with large doses administered via intraperitoneal instillation or in patients with myasthenia gravis
Macrolides (erythromycin, azithromycin, clarithromycin)	Nausea, vomiting, “burning” stomach, cholestatic jaundice, ototoxicity, prolonged QT interval	Oral administration: azithromycin and clarithromycin associated with less nausea than erythromycin Cholestatic jaundice reported for all erythromycin salts, most common with estolate Ototoxicity most common with high doses in patients with renal or hepatic failure Torsades de Pointes and increased risk of cardiac death associated with increased QT interval
Telithromycin	Hepatotoxicity; upper GI	Severe, sometimes fatal hepatotoxicity associated with telithromycin
Clindamycin	Diarrhea	Most common adverse effect. High association with antibiotic-associated colitis and *Clostridioides difficile*
Tetracyclines (including	Allergic	

Antibiotics	Side Effects	Comments
tigecycline)		
	Photosensitivity	
	Drug interactions	Decreased oral bioavailability with multivalent cations (less so with doxycycline). Similar to that stated in the Quinolones section
	Teeth and bone deposition and discoloration	Avoid in pediatrics (<8 years old), pregnancy, and breast-feeding
	GI	Upper GI predominates
	Hepatitis	Primarily in pregnancy or the elderly
	Vestibular	Associated with minocycline, particularly high doses
Vancomycin	“Red man syndrome”: hypotension, flushing	Associated with rapid infusion of vancomycin. More common with higher doses
	Nephrotoxicity	Reversible nephrotoxicity with high doses or in combination with other nephrotoxins
	Ototoxicity	Only with receipt of concomitant ototoxins such as aminoglycosides
	Phlebitis	Needs large volume dilution
Dalfopristin/quinupristin	Phlebitis	Generally requires central line administration
	Myalgia	Moderate to severe in many patients
	Increased bilirubin	
Daptomycin	Myalgia	Primarily at high doses and reversible

Antibiotics	Side Effects	Comments
Linezolid (tedizolid)	Thrombocytopenia, neutropenia, anemia, MAO inhibition, neuropathy	Bone marrow suppression and neuropathy duration- and dose-dependent with linezolid. Tedizolid may have less association with bone marrow suppression and neuropathy.
Dalbavancin, oritavancin, telavancin	Renal toxicity and prolonged QT with telavancin	
Sulfonamides	GI	Nausea, diarrhea
	Hepatic	Cholestatic hepatitis
	Rash	Exfoliative dermatitis, Stevens–Johnson syndrome. Rash more common in HIV
	Hyperkalemia	Hyperkalemia because of trimethoprim (as a component of trimethoprim-sulfamethoxazole)
	Bone marrow	Neutropenia, thrombocytopenia. More common in HIV
	Kernicterus	Caused by unbound drug in the neonate. Premature liver cannot conjugate bilirubin. Sulfonamide displaces bilirubin from protein, resulting in excessive free bilirubin and kernicterus
Chloramphenicol	Anemia	Idiosyncratic irreversible aplastic anemia (rare). Reversible dose-related anemia
	Gray syndrome	Caused by inability of neonates to conjugate chloramphenicol
Quinolones	GI	Nausea, vomiting, diarrhea

Antibiotics	Side Effects	Comments
	Prolonged QT	Moxifloxacin; possibly all quinolones as a class
	Drug interactions	Decreased oral bioavailability with multivalent cations
	CNS and peripheral neuropathy	Altered mental status, confusion, seizures. Neuropathy can be long term.
	Cartilage toxicity	Toxic in animal model. Despite this toxicity, appears safe in children including patients with cystic fibrosis
	Tendonitis or tendon rupture	Common in elderly, renal failure, concomitant glucocorticoids
	Dysglycemia	Hypo- and hyperglycemia
Antifungals		
Amphotericin B products	Nephrotoxicity	Common. May depend on patient sodium load. Caution with concomitant nephrotoxins (eg, aminoglycosides, cyclosporine)
	Hypokalemia	Predictable. Likely associated with renal tubular excretion of potassium. More common in patients receiving concomitant piperacillin-tazobactam
	Hypomagnesemia	Less commonly observed than hypokalemia
	Anemia	Long-term adverse effect. Similar to anemia of chronic disease
Caspofungin, micafungin, anidulafungin	Mild LFT increase with concomitant cyclosporine	Anidulafungin is reconstituted with alcohol (about the equivalent of a beer)

Antibiotics	Side Effects	Comments
Flucytosine	Neutropenia, thrombocytopenia	Secondary to metabolism of flucytosine to fluorouracil. More commonly observed with flucytosine levels >100 µg/mL. More common in patients with HIV
	Hepatitis	Usually moderate increase in LFT. Rarely clinical hepatitis but higher associations at levels >100 µg/mL
Ketoconazole (fluconazole, isavuconazole, itraconazole, posaconazole, voriconazole)	Drug interactions	Decreased oral bioavailability of ketoconazole tablet, and itraconazole capsules with increased gastric pH. Azoles are CYP450 substrates and also inhibitors of CYP450 3A4 and other CYP isoenzymes. voriconazole most likely to be associated with CYP drug interactions
	Upper GI	Dose-dependent and associated with all azoles
	Hepatitis	Ranges from mild increase in LFTs (AST, ALT) to occasional fatal hepatitis. More likely with voriconazole than other azoles
	Gynecomastia, decreased libido	More common with high-dose ketoconazole (>400 mg/day). Less common with other azoles
	Visual disturbance	Unique to voriconazole, particularly first week of therapy
	Squamous cell carcinoma	Long-term voriconazole
	Periostitis	Long-term voriconazole
Antivirals (Excluding Antiretrovirals and Hepatitis Antivirals)		

Antibiotics	Side Effects	Comments
Acyclovir	Phlebitis	Caused by poor solubility of IV preparation. Reported in 1%–20% of cases
	Renal failure	Low solubility of acyclovir associated with renal failure. Dehydrated patients, as well as rapid infusions, predispose to toxicity
	CNS	1% incidence in AIDS. Increased incidence with doses in excess of 10 mg/kg/day
Cidofovir	Nephrotoxicity	Commonly observed and often severe
Foscarnet	Nephrotoxicity	Occurs in up to 60% of patients. May be prevented with normal saline bolus before dose. Frequent monitoring of renal function imperative
	Mineral and electrolyte abnormalities	Hypo- or hypercalcemia, hypo- and hyperphosphatemia, hypomagnesemia, hypokalemia. Increased risk of cardiomyopathy and seizures
	Anemia	Anemia in 33%; usually manageable with transfusions and discontinuation of foscarnet
	Nausea, vomiting	
Ganciclovir	Neutropenia, thrombocytopenia	Increased incidence in AIDS. Increased incidence with doses in excess of 10 mg/kg/day
	Hepatitis	Usually mild to moderate increase in LFT

Antibiotics	Side Effects	Comments
Letermovir	Drug interactions Bloating, swelling, rapid weight gain, tingling of hands and feet	Substrate of CYP450 and p-glycoprotein
Oseltamivir	Nausea	
Ribavirin	Oral ribavirin: anemia Inhaled ribavirin: bronchospasm Inhaled ribavirin: bronchospasm Environmental concerns	Environmental concerns with inhaled ribavirin stem from the potential safety of the drug and exposure to health care personnel

AIDS, acquired immunodeficiency syndrome; CNS, central nervous system; EBV, Epstein–Barr virus; GI, gastrointestinal; HIV, human immunodeficiency virus; IV, intravenous; LFT, liver function tests; MAO, monoamine oxidase.

Concomitant Disease States

Concomitant disease states should also be considered in the selection of therapy. As discussed, older patients with hearing deficits are poor candidates for potentially ototoxic aminoglycoside therapy. Patients with diabetes or kidney transplant with candidemia may be better treated with fluconazole or an echinocandin rather than nephrotoxic amphotericin. Patients with a preexisting seizure history should not receive imipenem if safer choices are available. In summary, drug toxicity must always be considered in the selection of antimicrobial therapy.

ANTIMICROBIAL COSTS OF THERAPY

CASE 62-1, QUESTION 9: What factors should be included in calculating the cost of R.G.'s antimicrobial therapy?

The true cost of antimicrobial therapy is difficult to quantify.[27] Although acquisition cost traditionally has been the primary factor in the overall cost of therapy, drug administration labor costs (ie, nursing and pharmacy) and the use of IV sets, piggyback bags, and infusion control devices must be included in the analysis. As a result, a drug administered several times daily, such as intravenous penicillin, will incur increased administration costs compared with one that requires once-a-day dosing, such as ceftriaxone.

Some drugs, such as aminoglycosides, with a high potential for toxicity, are associated with additional costs because of pharmacokinetic and laboratory monitoring (eg, aminoglycoside serum concentrations, serum creatinine, and audiometry) that are not required for other agents,[28] such as the third-generation cephalosporins and quinolones. If meropenem with or without ciprofloxacin had been selected for R.G., this therapy would be expected to be associated with relatively few laboratory costs. However, the broad spectrum of activity[29] of these agents, potential for misuse, and development of resistance and superinfection could ultimately result in increased costs, including those to society.

Costs that are difficult to quantitate include those associated with failure of antimicrobial therapy and antimicrobial toxicity. Ineffective or toxic therapy can prolong hospitalization and may require expensive interventions, such as hemodialysis,[28] mechanical ventilation, and ICU admission. The net effect of these latter costs is usually significantly greater than the acquisition and administration costs of antimicrobial therapy.

In summary, determining the true cost of antimicrobial therapy is complex. Acquisition cost, IV bags, infusion controllers, and labor must be incorporated into the analysis. Although they are difficult to estimate, other costs, including because of antibiotic toxicity, superinfection and failure of therapy, should also be considered.

ROUTE OF ADMINISTRATION

Case 62-1, Question 10: The *Serratia* was determined to be susceptible to ciprofloxacin. Oral ciprofloxacin was considered for the treatment of R.G.'s presumed *Serratia* pneumonia, but the IV route was prescribed. Is the selection of the oral route of administration of ciprofloxacin reasonable?

The proper route of antibiotic administration depends on many factors, including the severity of infection, antimicrobial oral bioavailability, and other patient factors. In patients who appear "septic," blood flow often is shunted away from the mesentery and extremities, resulting in unreliable bioavailability from the gastrointestinal (GI) tract and muscles, respectively. Consequently, hemodynamically unstable patients should always receive antimicrobials by the IV route to ensure therapeutic antimicrobial levels. Furthermore, drug interactions with certain oral agents can result in subtherapeutic serum concentrations (eg, reduced bioavailability associated with concomitant quinolone and antacid administration, and decreased absorption of itraconazole with concurrent proton-pump inhibitor [PPI] therapy). Although clinical practice for some diseases states (such as endocarditis and osteomyelitis) has historically required that antibiotics be administered intravenously for the entire duration of therapy (4–6 weeks), a short initial course of IV therapy, followed by oral therapy for the remainder of the treatment is a reasonable option.[30,31] Early switch to oral therapy has potential benefits, including reduced IV catheter infection, greater adherence to the antimicrobial therapy, and increased patient satisfaction and quality of life.

R.G. is clinically septic with a possible *Serratia* pneumonia. Considering his unstable state, the bioavailability of oral ciprofloxacin cannot be guaranteed; thus, he should be treated with IV antimicrobials.

ANTIMICROBIAL DOSING

Case 62-1, Question 11: What dose of IV ciprofloxacin should be given to R.G.? What factors must be taken into account in determining a proper antimicrobial dose?

The choice of antimicrobial dose is based on many factors. **Table 62-9** provides a guide for the dosing of more commonly administered antimicrobials. The appropriate dosage should be based on well-designed trials in the treatment of a specific infection. Patient-specific factors, including weight, site of infection, and route of elimination, must also be considered in dosage selection. The patient's weight is important, particularly for agents with a low therapeutic index (eg, aminoglycosides, liposomal amphotericin, vancomycin); these drugs should be dosed on a milligram per kilogram per day basis. Obesity may require dosing based on an adjusted weight for some antibiotics. Other agents with a more favorable adverse effect profile, such as cephalosporins, are less likely to require weight-specific dosing in most disease states.

Table 62-9
Adult Antimicrobial Dosing Guidelines for Hospitalized Patients (Selected Drugs)[a]

Drug	CrCl >50 mL/minute	CrCl 10–50 mL/minute	CrCl <10 mL/minute (ESRD not on HD)	Dialysis (HD or CRRT)
Acyclovir	*Herpes simplex infections* 5 mg/kg/dose IV every 8 hours	5 mg/kg/dose IV every 12–24 hours	2.5 mg/kg IV every 24 hours	HD: 2.5 mg/kg IV × 1 now; then 2.5 mg/kg every evening (give after HD on HD days) CRRT: 5 mg/kg every 24 hours
	HSV encephalitis/Herpes zoster 10 mg/kg/dose IV every 8 hours	10 mg/kg/dose IV every 12–24 hours	5 mg/kg IV every 24 hours	HD: 5 mg/kg IV ×1 now; then 5 mg/kg every evening (give after HD on HD days) CRRT: 5–10 mg/kg every 12–24 hours
Ampicillin	*Meningitis or endovascular infection* 2 g IV every 4 hours *Uncomplicated infection* 2 g IV every 6 hours	2 g IV every 6 hours	1 g IV every 8–12 hours	HD: 1–2 g IV every 12 hours CRRT: 1–2 g IV every 6 hours
Ampicillin/sulbactam	3 g IV every 6 hours	1.5 g IV every 6 hours	1.5 g IV every 12 hours	HD: 1.5–3 g IV every 12 hours CRRT: 1.5 g IV every 6 hours
Aztreonam	2 g IV every 8 hours	2 g IV every 12 hours	1 g IV every 12 hours	HD: 1 g IV ×1 now; then 1 g every evening (give after HD on HD days) CRRT: 2 g IV every 12 hours
Cefazolin	*Gram negative or complicated gram positive* 2 g IV every 8 hours *Uncomplicated gram positive* 1–2 g IV every 8 hours	1–2 g IV every 12 hours	1 g IV every 24 hours	HD: 2 g after HD only CRRT: 2 g IV every 12 hours
Caspofungin Severe hepatic dysfunction: 70 mg LD, then 35 mg IV daily	LD: 70 mg × 1, then 50 mg every 24 hours Increase maintenance dose to 70 mg when given with phenytoin, rifampin, carbamazepine, dexamethasone, nevirapine, efavirenz	No change	No change	No change
Cefepime *Less severe infections* *Febrile neutropenia, meningitis, pseudomonas infections, patients who are critically ill*	>60 mL/minute 2 g IV every 12 hours 2 g IV every 8 hours	30–60 mL/minute: 2 g IV every 24 hours 2 g IV every 12 hours 10–30 mL/minute: 1 g IV every 24 hours 2 g IV every 24 hours	<10 mL/minute 500 mg IV every 24 hours 1 g IV every 24 hours	HD: 2 g after HD only CRRT: 2 g IV every 12 hours
Ceftazidime	2 g IV every 8 hours	2 g IV every 12–24 hours	500 mg IV every 24 hours	HD: 1 g after HD only CRRT: 2 g IV every 12 hours
Ceftriaxone *Meningitis*: 2 g every 12 hours *Endocarditis and osteomyelitis*: 2 g every 24 hours	1 g IV every 24 hours	No change	No change	No change

Drug	CrCl >50 mL/minute	CrCl 10–50 mL/minute		CrCl <10 mL/minute (ESRD not on HD)	Dialysis (HD or CRRT)
Ciprofloxacin[IV-PO] *Pseudomonas infections* *Severe infections*	400 mg IV every 12 hours 500–750 mg PO every 12 hours 400 mg IV every 8 hours 750 mg PO every 12 hours	30–50 mL/minute No change 250-500 mg PO every 12 hours No change		<30 mL/minute 200–400 mg IV every 24 hours 250–500 mg PO every 24 hours 200–400 mg IV every 12–24 hours 750 mg PO every 24 hours	HD: 400 mg IV every 24 hours or 500 mg PO every 24 hours (give after HD on HD days) CRRT: 400 mg IV every 12 hours
Clindamycin	600–900 mg IV every 8 hours	No change		No change	No change
Daptomycin Not effective in the treatment of pneumonia	4–10 mg/kg IV every 24 hours Dose depends on indication	<30 mL/minute 4–10 mg/kg IV every 48 hours			HD: 4–10 mg/kg IV every 48 hours CRRT: 4–10 mg/kg IV every 48 hours
Doxycycline[IV-PO]	100 mg IV/PO every 12 hours	No change		No change	No change
Ertapenem	1 g IV every 24 hours	<30 mL/minute 500 mg IV every 24 hours			HD: 500 mg every 24 hours CRRT: 500 mg every 24 hours
Ethambutol	15–20 mg/kg PO every 24 hours	<30 mL/minute 15–25 mg/kg three times/week			HD: 15–25 mg/kg three times/week (after HD) CRRT: 15–25 mg/kg three times/week
Fluconazole[IV-PO]	*Oropharyngeal candidiasis* 100 mg every 24 hours *Esophageal candidiasis* 200 mg every 24 hours *Severe infection* Loading dose of 800 mg then 400 mg every 24 hours	50–200 mg IV/PO every 24 hours		50–100 mg IV/PO every 24 hours	HD: 400 mg after HD only CRRT: 400–800 mg every 24 hours
Flucytosine (5FC)	*Meningitis* 25 mg/kg/dose PO every 6 hours	25–50 mL/minute 25 mg/kg/dose PO every 12 hours	10–25 mL/minute 25 mg/kg/dose PO every 24 hours	12.5 mg/kg/dose PO every 24 hours	HD: 12.5–25 mg/kg PO every 24 hours CRRT: 12.5–37.5 mg/kg/dose PO every 12–24 hours

Nafcillin *Meningitis, osteomyelitis, endovascular infection*	1–2 g IV every 4–6 hours 2 g IV every 4 hours	No change		No change	No change
Penicillin G *Meningitis, endovascular infection*	2–3 MU IV every 4–6 hours 3–4 MU IV every 4–6 hours	1–2 MU IV every 4–6 hours		1 MU IV every 6 hours	HD: 1 MU IV every 6 hours CRRT: 2 MU IV every 4–6 hours
Piperacillin/-tazobactam (Zosyn) *Documented/suspected Pseudomonas infections*	3.375–4.5 g IV every 6–8 hours 4.5 g every 6 hours for CrCl >20 mL/minute	3.375–4.5 g every 6–8 hours		2.25 g every 8 hours	HD: 2.25 g IV every 8 hours CRRT: 4.5 g IV every 8 hours or 3.375 g IV every 6 hours
Posaconazole Must be administered with high-fat meal or nutritional shake, eg, Ensure *Neutropenia prophylaxis*	400 mg PO every 12 hours or 200 mg PO every 6 hours 200 mg PO every 8 hours	No change		No change	No change
Pyrazinamide	20–25 mg/kg/day PO every 24 hours	<30 mL/minute 25–35 mg/kg three times/week			HD: 25–35 mg/kg three times/week after HD CRRT: 25–35 mg/kg three times/week
Rifampin *Mycobacterial infection* *Endocarditis* *Prosthetic device infection*	600 mg PO every 24 hours 300 mg PO every 8 hours 450 mg PO every 12 hours	No change		No change	No change
Tigecycline Severe hepatic disease: 100 mg IV ×1, then 25 mg IV every 12 hours	100 mg IV × 1, then 50 mg IV every 12 hours	No change		No change	No change
Tobramycin (and gentamicin) *Gram-negative infection* Dose is based on ideal body weight (IBW) except in patients who are obese or those under their IBW. Use actual body weight if patient weight is <IBW. Use adjusted body weight if patient is obese (calculations, see below).	For CrCl >60 mL/minute, not morbidly obese or fluid overloaded, give once-daily regimen: 7 mg/kg/dose IV every 24 hours. For those patients not qualifying for once-daily dosing, see conventional dosing below.				

Drug	CrCl >50 mL/minute		CrCl 10–50 mL/minute		CrCl <10 mL/minute (ESRD not on HD)	Dialysis (HD or CRRT)
For conventional dosing peak and trough levels should be monitored.	>60 mL/minute 1.6 mg/kg IV every 8 hours		40–60 mL/minute 1.2–1.5 mg/kg every 12–24 hours		<20 mL/minute 2 mg/kg loading dose, then follow drug levels	HD: 2 mg/kg IV × 1 then 1 mg/kg IV after HD CRRT: 2 mg/kg IV × 1 then 1.5 mg/kg IV every 24 hours
TMP/SMX[IV-PO] When switching to oral therapy, consider that a single-strength tablet has 80 mg of TMP, a double-strength tablet 160 mg of TMP.	*Systemic GNR infections* 10 mg TMP/kg/day IV divided every 6–12 hours *Pneumocystis pneumonia* 15–20 mg TMP/kg/day IV divided every 6–8 hours		5–7.5 mg TMP/kg/day IV divided every 12–24 hours 10–15 mg TMP/kg/day IV divided every 12–24 hours		2.5–5.0 mg TMP/kg IV every 24 hours 5–10 mg TMP/kg IV every 24 hours	HD: 2.5–5 mg TMP/kg/day every 24 hours CRRT: 5–7.5 mg TMP/kg/day divided every 12–24 hours
Vancomycin *Uncomplicated infections* *Serious infections*	>60 mL/minute 15–20 mg/kg IV every 8–12 hours	40–60 mL/minute 10–15 mg/kg IV every 12–24 hours	20–40 mL/minute 5–10 mg/kg IV every 24 hours	10–20 mL/minute 5–10 mg/kg IV every 24–48 hours	<10 mL/minute 10–15 mg/kg IV loading dose ×1; redose according to serum levels	HD: 15–20 mg/kg load, then 500 mg IV after HD only CRRT: 10–15 mg/kg IV every 24 hours
Round dose to 250 mg, 500 mg, 750 mg, 1 g, 1.25 g, 1.5 g, 1.75 g, or 2 g (maximum 2 g/dose). AUC should be calculated using Bayesian-derived monitoring software or hand calculated by using two levels (ideally a peak and trough from the same dosing interval at steady state). If using Bayesian-derived AUC monitoring software, a single level of vancomycin can be taken, regardless of timing (although a trough is preferable). If using hand calculation of AUC, peak levels should be obtained 1–2 hours after infusion and trough levels should be obtained within 30 minutes before the next dose (assuming steady state is achieved). AUC:MIC target is 400–600 m*h/L.						
Voriconazole[IV-PO]	LD = 400 mg every 12 hours × 1 day, then 200 mg every 12 hours (PO)		No change		No change[b]	No change[b]
PO should be used when possible, as oral bioavailability >95%. IV dose: LD = 6 mg/kg/dose every 12 hours × 1 day, then 4 mg/kg/dose every 12 hours.						

CrCl, creatinine clearance; CRRT, continuous renal replacement therapy (assumes an ultrafiltration rate of 2 L/hour with continuous venovenous hemofiltration and an ultrafiltration rate of 1 L/hour and dialysate flow rate of 1 L/hour with continuous venovenous hemodiafiltration and residual native glomerular filtration rate <10 mL/minute); ESRD, end-stage renal disease; GNR, gram-negative rod HD, intermittent (high-flux) hemodialysis (when administering a daily dose with HD, the drug should be administered after the HD session); HSV, herpes simplex virus; IV, intravenous; IV-PO, high oral bioavailability (consider initiating with or switching to PO therapy when patient tolerating orals); LD, loading dose; MRSA, methicillin-resistant *Staphylococcus aureus*; PO, by mouth; SCr, serum creatinine.

[a]Doses are those recommended for systemic infections in hospitalized patients commonly treated with these agents for moderate/severe infections. More mild infection may require decreased doses compared with moderate-to-severe infection. Dosing guidelines may differ in other institutions.

Estimate of renal function using Cockcroft and Gault equation: CrCl (mL/minute) = (140 − age) × Wt (kg)/72 × SCr (mg/dL) (for females multiply by 0.85).

Ideal body weight equation:

Males: IBW = 50 kg + 2.3 kg for each inch over 5 feet.

Females: IBW = 45.5 kg + 2.3 kg for each inch over 5 feet.

Adjusted body weight (consider if >120% IBW): ABW = IBW + 0.4 (actual weight − IBW).

[b]The use of the IV formulation should be avoided in patients with CrCl <50 mL/minute owing to accumulation of IV vehicle and is contraindicated in ESRD and hemodialysis. May require dose adjustment in hepatic dysfunction.

Site of Infection

Different doses are required for different infections. An uncomplicated urinary tract infection requires lower doses considering the high urinary drug concentrations achieved with most renally cleared agents. In contrast, a more serious upper urinary tract infection, such as pyelonephritis, requires increased antibacterial doses to ensure therapeutic drug levels in both tissue and serum.

Anatomic and Physiologic Barriers

Anatomic and physiologic barriers must also be considered in recommending a dosing regimen. For example, penetration into CSF requires high antibacterial doses to ensure adequate drug concentrations at the site of infection.[32] Vitreous humor[33] and the prostate gland[34] are additional examples of sites in which therapeutic antimicrobial concentrations are more difficult to achieve.

Route of Elimination

Route of elimination is another consideration in the dosage calculation for those drugs that are dependent on the kidney for clearance. In general, antimicrobials are eliminated renally or nonrenally (metabolic and/or biliary). Renal function can be estimated via 24-hour urine collection or with equations, such as Cockcroft and Gault[35]:

$$\text{Creatinine clearance} = ([140 - \text{age}] \times [\text{weight in kg}])/(72 \times \text{SCr})$$

Many antimicrobials (eg, most β-lactams) are eliminated by the kidney (Table 62-9). In contrast, ceftriaxone and most antistaphylococcal penicillins (eg, nafcillin, oxacillin, and dicloxacillin) are eliminated both renally and nonrenally. Aminoglycosides, vancomycin, acyclovir, and ganciclovir are cleared primarily by the kidney. Thus, dosage adjustment is recommended for these drugs in patients with renal failure (Table 62-9). Because azithromycin, clindamycin, and metronidazole are primarily eliminated by the liver, no dose reduction is required in renal failure. Using the Cockcroft and Gault equation, R.G.'s age (63 years), weight (154.32 pounds [70 kg]), and current serum creatinine (3.8 mg/dL) result in a calculated creatinine clearance of 14 mL/minute. R.G. normally should receive an IV dosage of ciprofloxacin at 400 mg every 12 hours but because of his reduced kidney function, he needs a lower dose (eg, 200 mg every 12 hours).

(Eq. 62-1)

Although renal function can be approximated with the use of the Cockcroft and Gault equation (or a similar equation), hepatic function is more difficult to evaluate. No standard liver function test (AST, ALT, alkaline phosphatase) has been demonstrated to correlate well with hepatic drug clearance. Some tests, such as PT, INR, and albumin, are markers of hepatic function, but even these tests do not clearly predict drug clearance. Patients receiving hemodialysis or continuous hemofiltration provide additional dosing challenges. Table 62-9 includes dosing recommendations for inpatients receiving hemodialysis or continuous hemofiltration.

Patient Age

It is important to note that most dosing information is derived from a younger, relatively healthy patient population. The newborn and the elderly have a decreased ability to clear drugs; thus, dosages for many agents are lower in neonatal and geriatric patients.

Fever and Inoculum Effect

The impact of other factors on the selection of an antimicrobial dose is less clear. Fever can both increase and decrease blood flow to mesenteric, hepatic, and renal organ systems,[36] and it can either increase or decrease drug clearance. Inoculum effect has been demonstrated when higher concentrations of a bacterial inoculum result in an increase in the MIC.[37] As an example, piperacillin may demonstrate an MIC of 8.0 μg/mL against *P. aeruginosa* at a concentration of 10^5 colony-forming units/mL (CFU/mL); however, at 10^9 CFU/mL, the MIC may increase to 32 to 64 μg/mL. This phenomenon is well recognized, particularly with β-lactamase–producing bacteria treated with β-lactam antimicrobials. The more stable the antimicrobial is to β-lactamase, the less the influence of the inoculum effect. Aminoglycosides, quinolones, and imipenem appear to be less affected by the inoculum effect than β-lactams. The inoculum effect probably is most relevant in the treatment of a bacterial abscess, in which extremely high concentrations of bacteria usually are present. As a result, antimicrobials that are more susceptible to the inoculum effect may require increased drug dosages for optimal outcomes in the treatment of abscesses.

PHARMACOKINETICS AND PHARMACODYNAMICS

Case 62-1, Question 12: R.G.'s respiratory status remains unchanged; thus, the ciprofloxacin is discontinued and cefepime and gentamicin are started empirically. The use of a prolonged 3-hour IV infusion of cefepime is being considered in R.G. In addition, the use of single daily dosing of gentamicin is being discussed. What is the rationale for these approaches, and would either be advantageous for R.G.?

β-Lactams, such as cefepime, are not associated with increased bacterial killing with increasing drug concentrations. Pharmacodynamic activity with β-lactams best correlates with the duration of time that antimicrobial levels are maintained above the

MIC.[38] The animal model suggests that β-lactam antimicrobials should be dosed such that their serum levels exceed the MIC of the pathogen as long as possible.[38] This observation appears to be most important in the neutropenic model, in which the use of a constant infusion more reliably inhibits bacterial growth compared with traditional intermittent dosing. An additional benefit of the use of constant infusions of β-lactams is that smaller daily doses appear to be as effective as higher doses administered intermittently. Other than this latter outcome, it is unclear, however, whether constant infusions have any distinct advantages or disadvantages compared with usual dosing of β-lactams. The efficacy of quinolones, vancomycin, and daptomycin best correlates with the peak plasma concentration to MIC ratio, or area under the curve (AUC) to MIC ratio.[38] In light of this pharmacodynamic principle, it is possible that ciprofloxacin was underdosed in this patient and contributed to the therapeutic failure, particularly if the MIC was in the upper range of susceptibility for this agent.

In the past, aminoglycosides were administered every 8 to 12 hours to achieve optimal peak serum levels (ie, 5–8 μg/mL, for gentamicin) in the treatment of serious gram-negative infection.[39],[40] With this past dosing strategy, gentamicin troughs of >2 μg/mL resulted in an increased risk for nephrotoxicity.[40],[41] The correlation of serum levels with both efficacy and toxicity has been questioned.[26] For vancomycin, troughs of 10 to 20 μg/mL have been traditionally recommended[42]; however, current recommendations suggest direct monitoring and calculation of the AUC via Bayesian pharmacokinetic software to achieve an AUC:MIC ratio of 400 to 600 μg/L.[43]

Several antimicrobials (eg, aminoglycosides) have been associated with a pharmacodynamic phenomenon known as a post-antibiotic effect (PAE). PAE is delayed regrowth of bacteria after exposure to an antibiotic (ie, continued suppression of normal growth in the absence of antibiotic levels above the MIC of the organism).[38],[44] As an example, if *P. aeruginosa* is cultured in broth, it will multiply to a concentration of 10^9 CFU/mL. If piperacillin is added in a concentration above the MIC for the organism, a reduction in the bacterial concentration is observed. As described, a β-lactam

antibiotic should be present in concentrations above the MIC to optimize its time-dependent killing. When piperacillin is removed from the broth, immediate bacterial growth takes place. If the above experiment is repeated with gentamicin, a reduction in bacterial CFU is observed. In contrast to that observed with β-lactam antibiotics, if the gentamicin is removed from the system, a lag period of 2 to 6 hours takes place before characteristic bacterial growth occurs. This lag period is defined as the PAE. A PAE has also been observed with quinolones and imipenem against gram-negative bacteria. Although most β-lactam antibiotics, such as antipseudomonal penicillins or cephalosporins, do not exhibit PAE against gram-negative organisms, PAE has been demonstrated in β-lactams against gram-positive pathogens such as *S. aureus.*

Once-Daily Dosing of Aminoglycosides

Because of PAE and other pharmacodynamic factors, certain antimicrobials may be dosed less frequently. The greatest clinical experience has been with the aminoglycosides in the treatment of gram-negative infection.[45],[46] Earlier data suggested that the maximal aminoglycoside peak level to MIC ratio correlates well with clinical response. Thus, the higher the achievable peak, the greater likelihood of a favorable outcome. Consequently, greater, less frequent doses of aminoglycosides should work at least as well as the more traditional lower, more frequent doses. Once-daily dosing of aminoglycosides in the treatment of gram-negative infection is as efficacious as traditional multiple daily dosing.[26]

Single daily dosing of aminoglycosides (ie, 5–6 mg/kg IV gentamicin every 24 hours) has been investigated primarily in patients with normal renal function, and few patients who are critically ill have been treated with this nontraditional regimen. Thus, patients in septic shock are less clear candidates for once-daily dosing. The utility and proper timing of serum aminoglycoside concentrations and association with clinical outcomes are debatable with nontraditional once-daily aminoglycosides.

In summary, the use of a prolonged IV infusion of cefepime is possible in R.G., but the benefit of this mode of administration is not clear. Considering the severity of R.G.'s infection and his elevated serum creatinine level, he is not a candidate for single daily dosing of aminoglycosides independent of the aminoglycoside-associated PAE, his current renal function requires a reduced gentamicin dose to treat his infection.

Antimicrobial Protein Binding

Case 62-1, Question 13: Ceftriaxone (Rocephin), rather than cefepime, is being considered for the treatment of R.G.'s infection. Ceftriaxone is more highly protein-bound than cefepime. Why is protein binding important in the selection of therapy?

Free (ie, unbound) rather than total drug levels best correlate with antimicrobial activity,[47] and the degree of protein binding may have important clinical consequences in some patients. Chambers et al[48] reported treatment failures with the highly protein-bound cefonicid (98% protein-bound) in patients with endocarditis caused by *S. aureus.* Despite achievable serum drug concentrations well above the MIC of the organism, breakthrough bacteremia occurred in three of four patients. Although total drug concentrations greatly exceeded the MIC of the pathogen, free concentrations were consistently below the level necessary to inhibit bacterial growth. Similar experiences have been reported with daptomycin (90%–93% protein-bound).[49] Thus, clinical cure appears to be more likely if unbound antibiotic concentrations exceed the MIC of the infecting organism. For β-lactams, the longer free unbound drug levels remain above the MIC, the likely better outcome. Although ceftriaxone is 85% to 90% protein-bound, the free concentrations probably remain far above the MIC throughout the entire dosing interval to optimally treat the *Serratia* in R.G.

ANTIMICROBIAL FAILURE

Antibiotic-Specific Factors

CASE 62-1, QUESTION 14: Despite "appropriate" treatment, R.G. is unresponsive to antimicrobial therapy. What antibiotic-specific factors may contribute to "antimicrobial failure"?

Antimicrobials may fail for various reasons, including patient-specific host factors, drug or dosage selection, and concomitant disease states. One of the most common reasons for antimicrobial failure is drug resistance.[50–52] Several clinically important pathogens have been associated with the emergence of resistance during the past decade, including *M. tuberculosis*,[53] enterococci,[54] gram-negative rods,[50] *S. aureus*,[55] *S. pneumoniae*,[56] and others. Of particular concern is the isolation of glycopeptide-resistant *S. aureus*[55] and multidrug-resistant *Acinetobacter* and *Pseudomonas.*[57] Development of resistance during therapy, although less common than initial intrinsic resistance, may also account for failure to respond to therapy. Organisms that produce extended-spectrum β-lactamase or amp C β-lactamases may be unresponsive to β-lactam therapy despite associated in vitro susceptibility.[58]

Superinfection may also play a role in the unsuccessful treatment of infection. Superinfection has taken place when a new pathogen resistant to the current antimicrobial regimen is isolated. If R.G.'s ceftriaxone-treated *Serratia* pneumonia subsequently worsens and a tracheal aspirate returns positive for *P. aeruginosa*, then supercolonization and, perhaps, superinfection have occurred.

Combination Therapy

Most infections can be treated with monotherapy (eg, an *E. coli* wound infection is treatable with a cephalosporin). Some infections, however, require two-drug therapy, including most cases of

enterococcal endocarditis and perhaps certain *P. aeruginosa* infections. Hilf et al studied 200 consecutive patients with *P. aeruginosa* bacteremia and demonstrated a 47% mortality in those receiving monotherapy (antipseudomonal β-lactam or aminoglycoside) versus 27% in those in whom two-drug therapy was used.[59] Thus, monotherapy appeared to contribute to antimicrobial failure in this specific study.

In contrast to the findings of the previous trial, almost all later investigations do not support the use of two drugs over monotherapy in the treatment of serious gram-negative infection, including *P. aeruginosa*.[60–62] An exception to this rule is bacteremia caused by *P. aeruginosa* in patients with neutropenia.

If two antimicrobials are used in the treatment of infection, one of three sequelae will result: indifference, synergism, or antagonism.[63] Indifference occurs when the antimicrobial effect of drug A plus that of drug B equals the anticipated sum activity of the two drugs. Although numerous definitions exist, synergism generally occurs when the addition of drug A to drug B results in a total antibiotic activity greater than the expected sum of the two agents. Antagonism occurs if the addition of drug A to drug B results in a combined activity less than the sum of drug A plus drug B. An example of antagonism is the combination of imipenem with a less β-lactamase–stable β-lactam, such as piperacillin.[64] If *P. aeruginosa* is exposed to imipenem and piperacillin, the imipenem induces the bacteria to increase its production of β-lactamase. Imipenem is remarkably β-lactamase–stable and is not degraded by this β-lactamase. In direct contrast, piperacillin is easily degraded by the β-lactamase. Thus, imipenem antagonizes the activity of piperacillin. Antagonism is not unique to antibacterials; itraconazole may antagonize amphotericin B in the treatment of certain fungal infections.[65]

Pharmacologic Factors

Case 62-1, Question 15: What pharmacologic or pharmaceutical factors can lead to failure of therapy?

Subtherapeutic dosing regimens are likely for agents with a low therapeutic index, such as the aminoglycosides. For example, a serious gram-negative pneumonia may not respond to aminoglycoside therapy with peak gentamicin serum levels of only 3 to 4 µg/mL.[26],[39] Considering that only 20% to 30% of the aminoglycoside penetrates from serum into bronchial secretions, only 0.5 to 1.0 µg/mL may exist at the site of infection,[66] a likely inadequate level to treat pneumonia. Another example of dosing contributing to antimicrobial failure centers on the lack of use of loading doses. Aminoglycosides or vancomycin regimens should be initiated with a loading dose, particularly in patients with renal failure. If the clinician neglects to use a loading dose, it may take several days before a therapeutic level is achieved. As described, another potential etiology for subtherapeutic antimicrobial levels and potential drug failure is reduced oral absorption because of drug interactions (eg, concomitant oral ciprofloxacin with antacids or iron).

An emerging problem relates to the use of vancomycin in the treatment of serious methicillin-resistant *S. aureus* (MRSA) infection. By CLSI standards, MRSA isolate with an MIC of 2 µg/mL is considered susceptible. Current vancomycin dosing schemes should achieve an AUC:MIC ratio of ≥400 to ensure maximal efficacy. However, similar patient outcomes have been observed with MRSA isolates with a vancomycin MIC of either ≥1.5 µg/mL or <1.5 µg/mL. Variability in susceptibility testing methods and documented failures with increased MICs[67] have led to the most current vancomycin guidelines recommending the use of alternative agents if the vancomycin MIC is ≥2 mg/L for MRSA isolates.[43] As described, the site of infection could also contribute to antimicrobial failure. Most antimicrobials concentrate in the urine, resulting in therapeutic levels even with receipt of low doses. However, in some infections, such as meningitis, prostatitis, and osteomyelitis, antimicrobial penetration to

the site of infection may be inadequate. Agents that penetrate well into these sites are associated with a more favorable outcome.

Another potential reason for antimicrobial failure is inadequate therapy duration. A female with a first-time uncomplicated cystitis may respond adequately to a 3-day course of an antibiotic. In contrast, patients with recurrent urinary tract infections are not candidates for this length of therapy, and failure is more likely with only 3 days of therapy.

Host Factors

Case 62-1, Question 16: What host factors may contribute to the failure of antimicrobial therapy?

Several host factors may limit the ability of an antibiotic to cure infection. Infection of prosthetic material (eg, IV catheters, orthopedic prostheses, mechanical cardiac valves, and vascular grafts) is difficult to eradicate without removal of the hardware. In most cases, surgical intervention is required for successful resolution of the infection. Consequently, to optimally treat R.G.'s IV catheter infection, removal of his central intravenous catheter should take place. Similar to infected prostheses, large, undrained abscesses are difficult, if not impossible, to treat with antimicrobial therapy. Such infections generally require surgical drainage for successful outcome.

Diabetic foot ulcer–associated cellulitis may not respond adequately to antimicrobial therapy. Reasons for antimicrobial failure in patients with diabetes include poor wound healing and reduced delivery of antibiotics to the infection site.

Immune status, particularly neutropenia or lymphocytopenia, can also influence infection treatment. Profoundly patients with neutropenia with disseminated *Aspergillus* infections are unlikely to respond to even the most appropriate antifungal therapy. Similarly, eradication of opportunistic infections (eg, because of cytomegalovirus, atypical mycobacteria, and cryptococci) in patients

with HIV/AIDS with extremely low CD4 lymphocyte counts, is difficult.

Once these factors have been eliminated as causes for antimicrobial failure, noninfectious sources (eg, malignancy, autoimmune disease, drug fever, as discussed) must be ruled out in the treatment of presumed and documented infection.

CASE 62-1, QUESTION 17: Other than initiation of adequate antimicrobial therapy, what adjunct measures can be considered in this patient with septic shock?

The 2016 Surviving Sepsis Campaign: International Guidelines for Management of Severe Sepsis and Septic Shock consultants developed key recommendations toward the early goal-directed resuscitation of the patient with sepsis.[68] These recommendations include the use of "sepsis bundles" (ie, multiple interventions taking place at the same time). Recommended key adjuncts include administration of broad-spectrum antibiotics within 1 hour of diagnosis of septic shock, administration of either crystalloid or colloid fluid resuscitation, and norepinephrine or dopamine to maintain mean arterial pressure of at least 65 mm Hg. In addition, stress-dose steroid therapy can be given to those patients whose BP is poorly responsive to fluid resuscitation and vasopressors. Although improved survival might be expected with adherence to such guidelines, the results have been mixed. Performance improvement programs have shown increased adherence to resuscitation and management sepsis bundles and reduced mortality in patients with sepsis, severe sepsis, or septic shock.[69] In contrast, in patients with early-identified septic shock who received intravenous antibiotics and adequate fluid resuscitation, an early, strict, goal-directed hemodynamic management protocol did not result in an improvement in outcomes.[70]

Antimicrobial Prophylaxis for Surgical Procedures

Daniel J. G. Thirion

CORE PRINCIPLES		CHAPTER CASES
1	Assessment of the risk of infection is based on patient and procedure risk factors.	**Case 63-1 (Question 1)**
2	Surgical antibiotic prophylaxis is indicated for patients at high risk for infection or in those at high risk for complications from postoperative infection. A contaminated wound requires presumptive therapy and an infected wound requires empiric therapy.	**Case 63-2 (Question 1)** **Case 63-7 (Question 1)**
3	The choice of prophylactic agent is based on the most likely pathogen associated with the surgical site infection. Institutional patterns of	**Case 63-2 (Question 2)** **Case 63-3 (Questions 1, 2)**

	pathogens, their resistance profiles, and antibiotic profiles impact agent selection.	**Case 63-4 (Question 1)** **Case 63-5 (Question 1)**
4	To maximize the benefit of prophylaxis, antibiotic administration should be completed in the 1 hour before incision to achieve adequate drug levels at the surgical site.	**Case 63-5 (Question 2)** **Case 63-8 (Question 1)**
5	The optimal dose for antimicrobials is based on weight, volume of distribution, and clearance rate.	**Case 63-2 (Question 3)**
6	Intravenous administration is most commonly used. Coadministration of an oral regimen is recommended in colorectal surgery.	**Case 63-6 (Question 3)**
7	Antimicrobials with shorter half-lives may require administration of an additional intraoperative dose in prolonged surgical cases.	**Case 63-5 (Question 3) Case 63-6 (Question 2)**
8	Single-dose preoperative prophylaxis is sufficient for most surgical procedures.	**Case 63-6 (Questions 1, 2)** **Case 63-8 (Question 1)**
9	Continuation of postoperative prophylaxis for up to 24 hours in cardiac surgery has been recommended by some professional organizations.	**Case 63-7 (Question 1)**
10	Continuation of prophylaxis beyond these time frames is not associated with improved outcomes and increases the	**Case 63-8 (Question 2)**

	risk of superinfections, emergence of resistance, adverse effects, and cost.	
11	Surgical site infections are classified as superficial or deep incisional and usually occur within 30 days of the surgical procedure. Deep organ or space infections can occur up to several months after surgery and up to a year after implantation of the prosthetic material.	**Case 63-9 (Question 1)**
12	Continuous quality improvement is critical in the prevention of surgical infection and should be overseen by a multidisciplinary team.	**Case 63-10 (Question 1)**

INTRODUCTION

Surgical site infection (SSI) occurs when a pathogenic organism multiplies in a surgical wound, leading to local and sometimes systemic signs and symptoms. They are among the most common health care–associated infections.[1,2] In developed countries, SSIs complicate surgical procedures in about 1% to 3% of cases but can be as high as 10%, depending on the surgical procedure and the patient.[2–4] In developing countries, infections occur in 6% to 15% of procedures, with data quality depending on the presence of postdischarge follow-up.[5] They put patients at risk for death, increase morbidity, extend the duration of hospitalization,[6,7] and are among the most expensive conditions encountered in U.S. hospitals,[8] associated with an estimated annual cost of $3.5 billion to $10 billion.[9]

Risk Factors for Infection and Implicated Pathogens

Risk factors for SSIs can be classified according to procedure-specific factors and patient characteristics.[7],[10],[11] Procedure-specific factors such as the surgeon's experience and technique, the duration of the procedure, and the operating room (OR) environment have an important influence on SSI rates (**Table 63-1**). The risk of SSI is influenced by host factors such as extremes of age, obesity, tobacco use, malnutrition, and comorbid states, including diabetes mellitus, glycemic control in patients with diabetes, remote infection, ischemia, oxygenation and body temperature during the procedure, colonization with microorganisms, immune status, and immunosuppressive therapy.[12]

Table 63-1
National Research Council Wound Classification

	Classification	Criteria	Infection Rate (%) Without Antibiotic Prophylaxis	Infection Rate (%) With Antibiotic Prophylaxis
I	Clean	No acute inflammation or entry into GI, respiratory, GU, or biliary tracts; no break in aseptic technique occurs; wounds primarily closed	>5	0.8
II	Clean-contaminated	Elective, controlled opening of GI, respiratory, biliary, or GU tracts without significant spillage; clean wounds with a major break in sterile technique	>10	1.3
III	Contaminated	Penetrating trauma (<4 hours old); major technique break or major spillage from GI tract; acute, nonpurulent inflammation	15–20	10.2
IV	Dirty	Penetrating trauma (>4 hours old); purulence or abscess (active infectious process); preoperative perforation of viscera	30–100	Therapeutic antibiotics

GI, gastrointestinal; GU, genitourinary.

Adapted with permission from Berard F, Gandon J. Postoperative wound infections: the influence of ultraviolet irradiation of the operating room and of various other factors. *Ann Surg*. 1964;160(suppl 2):1–192.

The likelihood of the development of an SSI is related to the degree of bacterial contamination during surgery, the virulence of the infecting organism, and host defenses.[7] Bacterial contamination can occur from exogenous sources (eg, the operative team, instruments, airborne organisms) or from endogenous sources (eg, the patient's

microflora of the skin, respiratory, genitourinary, or gastrointestinal [GI] tract).[11] Microbial flora of the skin from the point of entry and manipulation of colonized sites such as the GI tract are the most common causes of SSIs. *Staphylococcus aureus* is the leading causing pathogen, followed by *Escherichia coli*, *Enterococcus faecalis*, and coagulase-negative staphylococci.[13] Implicated pathogens vary according to surgical site. *E. coli* is the most common pathogen associated with abdominal surgical infection, whereas *S. aureus* is commonly associated with cardiac, orthopedic, and obstetric/gynecologic surgical infections and coagulase-negative staphylococci is often associated with transplant surgical infection.[13] Fungal infections are especially of concern in patients with risk factors (ie, immunosuppression). *Candida* species are the predominant fungi causing SSIs in solid organ transplant recipients.[14,15] Less frequently, *Aspergillus* species have been associated with infections following lung transplantation.[15] **Tables 63-2** and **63-3** list pathogens commonly associated with specific surgical procedures.[12,13]

Table 63-2
Suggested Prophylactic Antimicrobial Regimens for Clean Surgical Procedures

Procedure	Predominant Organisms	Recommended Agent(s)[a,b,c,d]	Alternative Agents[a,b]
Neurosurgery			
Craniotomy and cerebrospinal fluid–shunting procedures and implantation of intrathecal pumps	*Staphylococcus aureus*, coagulase-negative staphylococci, *Propionibacterium acnes*	Cefazolin	Clindamycin, vancomycin
Ophthalmic Surgery			
Cataract procedures	Coagulase-negative staphylococci	Neomycin–polymyxin B–gramicidin, gatifloxacin, or moxifloxacin[d,e]	None
Cardiac Surgery			
All with sternotomy, cardiopulmonary bypass, pacemaker, and automated defibrillator placement	*S. aureus*, coagulase-negative staphylococci, gram-negative bacilli	Cefazolin	Cefuroxime, clindamycin, vancomycin
Vascular Surgery			
Vascular (aortic resection, groin incision, prosthesis)	*S. aureus*, coagulase-negative staphylococci, gram-negative enterics	Cefazolin	Clindamycin, vancomycin
Orthopedic Surgery			
Spinal procedure, total joint replacement, internal fixation of fractures	*S. aureus*, coagulase-negative staphylococci, enterococci, gram-negative bacilli	Cefazolin	Clindamycin, vancomycin
Plastic Surgery			
Tissue transplantation and skin grafts and flaps	*S. aureus*, other staphylococci, streptococci, gram-negative enterics	Cefazolin, ampicillin–sulbactam	Clindamycin, vancomycin

[a]Dosing of antibiotics is ampicillin–sulbactam 3 g, cefazolin 2 g in patients weighing up to 264 pounds (120 kg) and 3 g if weighing >264.55 pounds (120 kg), cefuroxime 1.5 g, cefoxitin 2 g, ciprofloxacin 400 mg, clindamycin 900 mg, gentamicin 5 mg/kg based on dosing weight and single dose, levofloxacin 500 mg, metronidazole 500 mg, moxifloxacin 400 mg, and vancomycin 15 mg/kg.

[b]Vancomycin and ciprofloxacin require longer infusion times and administration should be started in the 2 hours before the incision.

[c]Addition of vancomycin to the antimicrobial regimen is recommended for patients with known methicillin-resistant *Staphylococcus aureus* (MRSA) colonization or prior MRSA infection, and addition of linezolid is recommended if there is known vancomycin-resistant enterococci (VRE) or prior VRE infection. If patient is colonized with MRSA and VRE, only administer linezolid.

[d]Addition of fluconazole to the antibiotic regimen is recommended for patients at high risk for fungal infection.

[e]Neomycin–polymyxin B–gramicidin, gatifloxacin, and moxifloxacin require topical administration of one drop every 5 to 15 minutes for five doses.

Table 63-3
Suggested Prophylactic Antimicrobial Regimens for Clean-Contaminated Surgical Procedures

Procedure	Predominant Organisms	Recommended Agent(s)[a,b,c,d]	Alternative Agents[a,b]
Head and neck surgery involving incisions through mucosa	Viridans group streptococci, *Staphylococcus aureus*, coagulase-negative staphylococci	Cefazolin + metronidazole	Ampicillin–sulbactam, clindamycin
Thoracic Surgery			
Lung resection, pneumonectomy, lobectomy, thoracotomy, thoracoscopy	*S. aureus*, coagulase-negative staphylococci, viridans group streptococci	Cefazolin	Clindamycin, vancomycin
Esophageal resection	Gram-negative enterics, gram-positive cocci, oropharyngeal anaerobes	Cefazolin[e]	Vancomycin + tobramycin
General Surgery			
Gastroduodenal surgery (only for procedures entering the stomach and the intestines)	Streptococci, *Candida albicans*, *S. aureus*, gram-negative enterics	Cefazolin	Clindamycin or vancomycin + aminoglycoside
Small bowel surgery[f]	*Escherichia coli*, *E. faecalis*, *Klebsiella* spp.	Cefazolin	Clindamycin + aminoglycoside or aztreonam or fluoroquinolone
Appendectomy (uncomplicated)	*E. coli*, *Bacteroides fragilis*, viridans group streptococci, *Pseudomonas aeruginosa*	Cefoxitin	Cefazolin + metronidazole, metronidazole + aminoglycoside
Hernioplasty and herniorrhaphy (open repair)	*S. aureus*, *E. coli*, *E. faecalis*, other gram-negative enterics, other gram-positive organisms	Cefazolin	Clindamycin, vancomycin
Pancreatic surgery (pancreaticoduodenectomy and pancreatectomy)	*E. coli*, *Klebsiella* spp., *Enterobacter* spp., *E. faecalis*	Ceftriaxone + ampicillin	Vancomycin + aminoglycoside
Hepatic (hepatectomy)	*E. coli*, *Klebsiella* spp., *Enterobacter* spp., *E. faecalis*	Ceftriaxone + ampicillin	Tobramycin + vancomycin
Biliary tract surgery (including cholecystectomy)	*E. coli*, *Klebsiella* spp., *S. aureus*, *E. faecalis*	Cefazolin	Clindamycin or vancomycin + aminoglycoside or aztreonam or fluoroquinolone

Procedure	Predominant Organisms	Recommended Agent(s)[a,b,c,d]	Alternative Agents[a,b]
Colorectal surgery[g]	*E. coli*, *E. faecalis*, *B. fragilis*, *S. aureus*, other gram-negative enterics	Cefazolin + metronidazole	Ampicillin–sulbactam, metronidazole + aminoglycoside
Gynecologic Surgery			
Cesarean section	*S. aureus*, *E. coli*, coagulase-negative staphylococci, *E. faecalis*	Cefazolin	Clindamycin + aminoglycoside
Hysterectomy (abdominal and vaginal)	*S. aureus*, *E. coli*, *E. faecalis*, *Bacteroides* spp.	Cefazolin	Clindamycin or vancomycin + aminoglycoside
Genitourinary Surgery			
With open or laparoscopic entry of the abdomen	*S. aureus*, *S. epidermidis*, gram-negative enterics, enterococci	Cefazolin	Clindamycin + aminoglycoside
With entry of the urinary tract (ureterectomy, prostatectomy, cystectomy)	*E. coli*, other gram-negative enterics, enterococci	Cefazolin	Fluoroquinolone, aminoglycoside with or without clindamycin
With entry of the gastrointestinal tract (use of bowel segments)	Gram-negative enterics, anaerobes, *S. aureus*	Cefazolin + metronidazole	Fluoroquinolone or aminoglycoside + metronidazole or clindamycin
Renal surgery (nephrectomy, percutaneous nephrolithotomy)	*E. coli*, *S. aureus*, coagulase-negative staphylococci	Cefazolin	Vancomycin
Transplant Surgery			
Heart and lung transplantations	Staphylococci, *Enterobacter* spp., *P. aeruginosa*	Cefazolin	Clindamycin, vancomycin
Pancreas transplantation (with or without kidney transplantation)	Staphylococci, *E. coli*, *Klebsiella* spp.	Cefazolin	Clindamycin or vancomycin + gentamicin or aztreonam or a fluoroquinolone
Liver transplantation	*Enterococcus* spp., staphylococci, *E. coli*	Piperacillin–tazobactam, cefotaxime + ampicillin	Clindamycin or vancomycin + gentamicin or aztreonam or fluoroquinolone
Kidney transplantation	Coagulase-negative staphylococci, *E. coli*, *P. aeruginosa*, enterococci	Cefazolin	Clindamycin or vancomycin + gentamicin or aztreonam or a fluoroquinolone

spp., species.

[a]Dosing of antibiotics is ampicillin–sulbactam 3 g, cefazolin 2 g in patients weighing up to 264.55 pounds (120 kg) and 3 g if weighing >264.55 pounds (120 kg), cefuroxime 1.5 g, cefoxitin 2 g, ciprofloxacin 400 mg, clindamycin 900 mg, gentamicin 5 mg/kg based on dosing weight and single dose, levofloxacin 500 mg, metronidazole 500 mg, moxifloxacin 400 mg, and vancomycin 15 mg/kg.

[b]Vancomycin and ciprofloxacin require longer infusion times and should be administered in the 2 hours before surgery.

[c]Addition of vancomycin to antimicrobial regimen is recommended for patients with known methicillin-resistant *Staphylococcus aureus* (MRSA) colonization or prior MRSA infection, and addition of linezolid is recommended if there is known vancomycin-resistant enterococci (VRE) or prior VRE infection. If patient is colonized with MRSA and VRE, only administer linezolid.

[d]Addition of fluconazole to the antibiotic regimen is recommended for patients at high risk for fungal infection.

[e]For esophageal resection with mucosal breach, add metronidazole to the antimicrobial regimen.

[f]For obstructed small bowel, cefazolin plus metronidazole is recommended.

[g]An oral regimen of neomycin plus erythromycin or metronidazole the day before surgery is recommended.

Microbial contamination can also occur from remote infections or colonized sites. Treatment of ongoing infections before surgery is recommended in an effort to minimize risks of contamination.[4],[11] The current consensus is that SSIs are caused either by endogenous pathogens adjacent to the surgical site or exogenous pathogens present in the surgical environment. Current guidelines recommend antimicrobial regimens covering pathogens likely to be encountered at the surgical site.[12] However, the majority of patients with positive wound culture do not develop postoperative infections, implying that wound culture is not the best predictive factor for SSIs.[16] The hypothesis of pathogens being carried from remote sites (eg, GI tract) to the damaged tissue as possible pathogenesis for SSIs is being proposed but remains to be validated.[16],[17]

Clinical Presentation

SSIs can be defined as superficial incisional (involving the skin and subcutaneous fat), deep incisional (involving fascia and muscle), or organ space.[18],[19] Typically, an infected incision site wound is red, warm, and purulent and sometimes swollen, tender, or painful. Poor wound healing or dehiscence (reopening of the incision) is highly suggestive of infection. An SSI can also involve any part of the anatomy (eg, organs or spaces), other than the incision, which was opened or manipulated during an operation.[4] The purulent drainage, if present, should be cultured to identify the causative pathogen and direct antimicrobial therapy. Empiric therapy directed against the most likely pathogens should be instituted while awaiting culture and sensitivity test results. Although most incision site infections are diagnosed shortly after surgery (within 30 days), some deep-seated infections present indolently for weeks to months.[4] Infection of surgically implanted prosthetic hardware may take place up to a year after the surgical procedure.[4]

Nonpharmaceutical Recommendations and Prevention Programs

SSIs are mostly preventable health care–associated infections. In addition to the administration of antimicrobial prophylaxis before surgery, preoperative, intraoperative, and postoperative interventions can reduce rates of infection related to surgical procedures.[4] In 2014, the Surgical Infection Prevention (SIP) project became the Surgical Care Improvement Project (SCIP) in an effort to include interventions that are not restricted to prophylactic antibiotic use. These evidence-based recommendations cover proper hair removal at the surgical site, glycemic control, and normothermia control.[4,7] Moreover, infection control procedures to minimize all sources of bacterial contamination, including patient and surgical team preparation, operative technique, and incision care, are compiled in appendix 1 of the Centers for Disease Control and Prevention guidelines for SSI.[4] The aim of international initiatives such as the World Health Organization (WHO) Global Guidelines for Prevention of Surgical Site Infections is to encourage best surgical practices and improve patient outcomes.[3] Implementation of adapted strategies nationally and locally is critical to reduce the risk of SSIs. Among institutions, such strategies should focus on engagement and education of medical teams as well as execution and evaluation of procedures.[7] Following American national recommendations, institution prevention programs should consider the Centers for Disease Control and Prevention guidelines, as well as the Society for Hospital Epidemiologists for America (SHEA) and the Infectious Disease Society of America (IDSA) guidelines.[4,20]

ANTIMICROBIAL PROPHYLAXIS

Prophylactic antibiotics are widely used in surgical procedures and account for substantial antibiotic use in hospitals worldwide.[21] The purpose of surgical antibiotic prophylaxis is to reduce the prevalence of postoperative wound infection. Appropriate use of prophylactic antimicrobial agents results in decreased patient morbidity and

hospitalization costs for many surgical procedures.[22] However, the benefits of prophylaxis are questionable for surgical procedures at low risk for infection (eg, urologic operations in patients with sterile urine).[12] Consequently, inappropriate or indiscriminate use of prophylactic antibiotics can expose the patient to unnecessary risk of drug toxicity and superinfections, promotes the selection of resistant organisms, and increases cost.[23–26]

ASSESSING ANTIMICROBIAL PROPHYLAXIS

Steps for assessment of surgical antimicrobial prophylaxis include indication for prophylaxis, choice of antibiotic, dosing, timing of administration, route of administration, redosing during the surgical procedure, and duration of prophylaxis. The selection of a prophylactic regimen should be based on the spectrum of activity of the agents and the most likely pathogens associated with the given surgical procedure, pharmacokinetic characteristics (eg, half-life), adverse event profile, selective pressure for bacterial resistance, and cost.[12] These principles are usually adapted into guidelines and recommendations according to local bacterial resistance patterns. At the bedside, agent selection should also be adapted according to patient characteristics including allergies, risk of specific adverse events, colonization status, and procedure-related events.[12] Optimal prophylaxis ensures that adequate concentrations of an appropriate antibiotic are present in the serum and tissue during the entire time the surgical wound is open and at risk for bacterial contamination.[4]

DETERMINING RISK FACTORS FOR INFECTION

CASE 63-1

QUESTION 1: C.P., a 78-year-old female with osteoarthritis, is hospitalized for an elective hip surgery. She is 65 inches (165 cm) tall, weighs 198 pounds (89.8

kg), and is a nonsmoker. The surgery is planned to last within the usual time frame of the operation, which is about 1 to 2 hours.

What is the risk of infection following surgery for her?

Measuring and predicting the risk of infection determines which patients should receive antibiotic prophylaxis. The Centers for Disease Control and Prevention Study on the Efficacy of Nosocomial Infection Control (SENIC) developed an index that included the level of wound contamination and three other criteria based on procedure-related and patient-related factors.[27] Modification of this tool has led to the National Nosocomial Infection Surveillance (NNIS) System Risk Index that takes into account the patient's preoperative assessment (American Society of Anesthesiologists Assessment),[28] the level of contamination of the procedure, the duration of the procedure, and the use of a laparoscope.[10] This last criterion was added because of the associated decreased incidence of infection with the introduction of laparoscopic procedures. Indexes such as these are particularly useful for comparison of performance among institutions and public reporting.

The evaluation of the level of risk of infection according to the NNIS Risk Index System is helpful to predict preoperative risk and justify surgical antibiotic prophylaxis use. It can be summarily understood by going through three steps. The first step is to determine the surgical wound class. Each surgical wound class is defined in Table 63-1. Surgical wound class II, III, or IV counts for 1 point. The second step is to determine the American Society of Anesthesiologists Assessment score. One point is assigned if the patient has nonincapacitating severe systemic disease, has life-threatening incapacitating systemic disease, or is not expected to survive without operation.[29] The third step is to determine whether the duration of the operation exceeds the standard T point as determined by the NNIS database.[30] Surgeries that last longer than the standard time are assigned 1 point. The addition of these risk factors results in a score ranging from 0 to 3.

C.P. is at relatively low risk for infection. There are no points as attributed according to the NNIS score because she will undergo a

clean surgery within the average time frame. Her American Society of Anesthesiologists score is 2, being known with mild systemic disease (obese, rheumatoid arthritis, age older than 60).

CLASSIFICATION OF SURGICAL SITE INFECTIONS

From 1960 to 1964, the National Academy of Sciences National Research Council conducted a landmark study of SSIs and formulated a widely used standard classification based on the risk of intraoperative bacterial contamination (see Table 63-1).[31] Current recommendations for surgical prophylaxis pertain to clean surgeries at high risk for complications and/or involving implantation of prosthetic material, clean-contaminated surgeries, and select contaminated wounds. Antimicrobials for dirty surgeries in which infection is already established are considered treatment instead of prophylaxis and are not discussed further in this chapter. Recommendations for site-specific prophylactic antimicrobial regimens according to suspected pathogens are listed in Tables 63-2 and 63-3; a detailed examination of clinical trials supporting these recommendations is presented elsewhere.[12]

Decision to Use Antimicrobial Prophylaxis

CASE 63-2

QUESTION 1: M.R., a 62-year-old 265-pound (120.2-kg) male, is admitted to the hospital with severe abdominal pain, nausea and vomiting, and temperature of 102.7 °F (39.3 °C). A diagnosis of acute cholecystitis is made, and M.R. is scheduled for open biliary tract surgery (cholecystectomy).

Why is antimicrobial prophylaxis warranted for M.R.?

Based on the risk factors for infection previously discussed, the decision whether a given patient should receive antimicrobial

prophylaxis depends on a number of factors. Antimicrobial prophylaxis should be given for surgical procedures (a) with a high rate of infection (ie, clean-contaminated or contaminated procedures), (b) involving the implantation of prosthetic materials, or (c) in which an infection would have catastrophic consequences.[12] Open biliary tract surgery is considered a clean-contaminated procedure and, therefore, carries a risk of surgical wound infection approaching 10% (see Tables 63-1 and 63-3). The risk factors for infection include age older than 70 years, diabetes mellitus, acute cholecystitis, obstructive jaundice, common duct stones, emergency procedures, pregnancy, immunosuppression, nonfunctioning gallbladder, or insertion of prosthetic device. Prophylaxis is recommended for all patients undergoing open biliary tract surgery.[12] Prophylaxis is not recommended for low-risk procedures such as elective laparoscopic cholecystectomy. Thus, prophylaxis is warranted in M.R.

Selection of an Antimicrobial Agent

Case 63-2, Question 2: An order for intravenous (IV) cefazolin 2 g on call to the OR is written for M.R. Why is this an appropriate (or inappropriate) antibiotic selection?

The selected prophylactic agent should be directed against likely infecting organisms (see Tables 63-2 and 63-3) but need not eradicate every potential pathogen. In general, pathogens associated with infection originate from the skin or the associated structures contiguous to the regions involved in the surgical procedure. Cefazolin has been proved effective for most surgical procedures, including biliary tract surgery, given that the goal of prophylaxis is to decrease bacterial counts below critical levels necessary to cause infection. Broad-spectrum agents, such as third-generation cephalosporins, should be avoided for prophylaxis because they are no more effective than is cefazolin and may alter microbial flora, increasing the emergence of microbial resistance to

these otherwise valuable agents. Therefore, cefazolin is an appropriate antibiotic selection.

Case 63-2, Question 3: The nurse mentions that the patient is obese. Would you make any dosing recommendations?

Given the need for appropriate concentrations effective against likely pathogens at the incision site, drug pharmacokinetic parameters must be considered. Physiologic changes in patients who are obese can alter drug pharmacokinetics and consequently impact the distribution, metabolism, and clearance of the drugs.[12] In patients who are obese, the altered drug distribution can result in a decrease in drug concentration in tissues that can lead to suboptimal drug concentration at incision time. Therefore, current guidelines suggest a 2-g cefazolin dose for all adults weighing <264.55 pounds (120 kg) and a 3-g dose for patients ≥264.55 pounds (120 kg).[12] Because M.R. falls into the ≥264.55-pound (120-kg) category, the recommended dose is 3 g.

Selection of an Antimicrobial Agent

CASE 63-3

Question 1: L.T., a 46-year-old female, has a recent history of abnormal uterine bleeding and vaginal discharge. Endometrial biopsy finding is positive for squamous cell carcinoma; however, there does not appear to be an invasive disease. The diagnosis is carcinoma in situ, and a vaginal hysterectomy is scheduled.

What would be an appropriate surgical prophylaxis antimicrobial regimen for L.T.?

The selection of a prophylactic regimen should be based on the spectrum of activity of the agents and the most likely pathogens associated with the given surgical procedure (see Tables 63-2 and 63-3), pharmacokinetic characteristics (eg, half-life), adverse event profile, impact on bacterial resistance selection, and cost.

The usefulness of antimicrobial prophylaxis in vaginal hysterectomies is well established and should be directed against vaginal microflora, including gram-positive and gram-negative aerobes and anaerobes (see Table 63-3).[32] The most-effective, yet most narrow-spectrum agent should be selected considering that the goal of prophylaxis is not to eradicate every potential pathogen but to reduce bacterial counts below a critical level necessary to cause infection. Cefazolin has been proved to be as effective a prophylactic agent as ceftriaxone for vaginal hysterectomy.[33] This finding reinforces the fact that a more broad-spectrum agent (eg, a third-generation cephalosporin) is unwarranted.

Similar to vaginal hysterectomy, cefazolin and numerous agents (cefotetan, cefoxitin, ampicillin–sulbactam, etc) decrease the incidence of postoperative surgical infection when the abdominal approach is used.[32],[34] As with vaginal hysterectomy, most trials have not revealed significant differences between first- and second-generation cephalosporins.[34] In contrast, Hemsell et al[35] observed a significantly higher incidence of major postoperative surgical infections in patients receiving the first-generation agent cefazolin when compared with the second-generation cephalosporin, cefotetan. Cefazolin exhibits a favorable toxicity profile and has a relatively long half-life (~1.8 hours), and a single dose has proven prophylactic efficacy.[33] Cefazolin also is considerably less expensive than are broader-spectrum agents and is currently recommended by the American College of Obstetricians and Gynecologists.[36] Although it has a broader spectrum of coverage, a single dose of cefoxitin would also be an appropriate choice for this patient.[32],[34]

Case 63-3, Question 2: Because cefoxitin has an increased spectrum of activity against the anaerobe *Bacteroides fragilis*, it is being considered as an alternative to cefazolin prophylaxis for L.T. Is this change in prophylaxis appropriate?

The second- and third-generation cephalosporins and ampicillin–sulbactam generally are not more effective than the first-generation cephalosporins for surgical prophylaxis in vaginal hysterectomy or in

gastroduodenal, biliary, and clean surgical procedures.[12] One exception to these findings is in the prevention of infection after colorectal procedures and, perhaps, hysterectomy. Several investigations have documented the failure of first-generation agents when used as prophylaxis in colorectal procedures, probably a consequence of their weak anaerobic coverage.[37] As stated previously, second- and third-generation agents and ampicillin–sulbactam generally are no more efficacious than is cefazolin and should not be used for surgical prophylaxis in most procedures. Cefoxitin, however, would be a reasonable choice in colorectal surgery or hysterectomy. Considering that this patient is having a hysterectomy, either cefazolin or cefoxitin is appropriate.

CASE 63-4

QUESTION 1: S.N., a 57-year-old female with rheumatoid arthritis and degenerative joint disease, has been admitted for total hip arthroplasty. She states that she had an anaphylactic reaction to penicillin in the past.

How does this allergy history impact the selection of surgical prophylaxis for S.N.?

Cefazolin is the preferred prophylactic agent for most clean procedures, including cardiac, neurologic, vascular, and orthopedic procedures (see Table 63-2). Although the risk of cefazolin cross-allergenicity to penicillin is relatively low, S.N. experienced a serious, accelerated reaction (hives, shortness of breath [SOB]) with penicillin; consequently, she should not receive cefazolin. The organisms most likely to cause postoperative infection after total hip replacement are *S. aureus* and coagulase-negative staphylococci (see Table 63-2). Nafcillin, cefazolin, and vancomycin possess excellent activity against *S. aureus*; however, the β-lactams have only marginal activity against coagulase-negative staphylococci such as *S. epidermidis*. Regardless, nafcillin (and cefazolin) should be avoided because of the penicillin allergy, and the preferred agent for S.N. is vancomycin.

Preoperative vancomycin 15 mg/kg should be administered IV slowly, for at least 60 minutes. This slow rate of infusion is necessary to reduce the risk of infusion-related hypotension.[38]

CASE 63-5

QUESTION 1: B.K., an 18-year-old female, reports severe acute abdominal pain and nausea; the pain is localized to the periumbilical region. B.K. has a temperature of 103.1 °F (39.5 °C). After initial examination by her pediatrician, she is admitted to the hospital with presumed appendicitis, and an exploratory laparotomy is scheduled.

What surgical antimicrobial prophylaxis should be ordered for B.K.?

As with colorectal surgery, the most likely infecting organisms in appendectomy are *Bacteroides* species and gram-negative enterics (see Table 63-3). On surgical inspection, if the appendix appears normal (not inflamed, without perforation), then antimicrobial prophylaxis is unnecessary.[39] If the appendix is inflamed without perforation, a single preoperative antibiotic dose is necessary. If the appendix is perforated or gangrenous (complicated), infection is already established, and postoperative treatment is warranted. The status of the appendix, however, cannot be determined before surgery; therefore, all patients should receive at least one preoperative dose of an appropriate antibiotic.[40] After surgical inspection of the appendix, the need for postoperative antibiotic therapy can be determined.

Based on the pathogens likely to be encountered, an antimicrobial agent with both aerobic and anaerobic activity should be used. Consequently, cefoxitin is an acceptable choice for prophylaxis.[41]

Timing of Antimicrobial Administration

CASE 63-5, QUESTION 2: The administration of IV cefoxitin for B.K. is scheduled on call to the OR. Why is the administration time for this antimicrobial appropriate (or inappropriate) for B.K.?

Classic animal studies conducted by Burke[42] and others[43] clearly demonstrated the need for therapeutic antibiotic concentrations in the bloodstream and in vulnerable tissue at the time of wound contamination. Bacteria were most likely to enter the tissue beginning with the initial surgical incision and continuing until the wound was closed; antibiotics administered >3 hours after bacterial contamination were ineffective in decreasing the rate of wound infection.[42],[43] This 2- to 3-hour period after the surgical incision was deemed the “effective” or “decisive” period for prophylaxis, when the animal’s wound was most susceptible to the beneficial effects of the antibiotic. This decisive period for administration of prophylactic antibiotics has been confirmed in humans to be somewhere in the 2 hours before incision as compared to earlier administration or any time after incision.[44–47] Investigation of the precise window for optimal outcomes demonstrated that narrowing the window from 60 to 30 minutes before incision for antimicrobials with a short half-life (eg, cephalosporins) does not reduce infection rates.[48]

For maximal efficacy, an antibiotic should be present in therapeutic concentrations at the incision site as early as possible during the decisive period and continuing until the wound is closed. Because an antibiotic administered postoperatively cannot achieve therapeutic concentrations during the decisive period, postoperative administration does not prevent postoperative wound infections, and infection rates are similar to those in patients who receive no antibiotics.[49]

Consequently, prophylactic antibiotics should be administered before the surgical procedure in the operative suite.[12] Prophylactic antibiotics are most effective when given within the 1-hour window before surgical incision; rates of infection increase significantly if antibiotics are administered >1 hour before incision or postoperatively.[46],[47] Administration of vancomycin and fluoroquinolones should begin in the 120 minutes before surgical incision because of the prolonged infusion times required for these drugs.[12] If a tourniquet is required to control blood flow to a limb during surgery, the evidence is insufficient to recommend administering the dose before or after inflation of the tourniquet.[4]

The “on-call” prescribing practice for surgical prophylaxis, as with B.K., has fallen into disfavor because the time between antibiotic administration and the actual incision may exceed 1 hour. This delay may result in subtherapeutic antibiotic concentrations during the decisive period.[12],[50] B.K.’s cefoxitin should be ordered preoperatively and should be administered in the OR within 1 hour of the surgical incision.

Case 63-5, Question 3: Will B.K. require a second dose of cefoxitin during the surgical procedure?

The duration of the surgical procedure and the half-life of the administered antibiotic should be considered when determining the need for an additional intraoperative dose. The longer the duration of the surgical procedure, particularly with short half-life antibacterials, the greater the incidence of postoperative infection.[45],[51],[52] Cefoxitin, with a half-life of ~ 0.7 to 1 hour, is effective in a single preoperative dose for most surgical procedures. For prolonged procedures, or those with major blood loss,[53],[54] additional intraoperative doses should be administered every two half-lives of the drug.[12] B.K. should require an additional intraoperative cefoxitin dose only if the surgical procedure is prolonged (>2 hours).

Route of Administration

CASE 63-6

Question 1: G.B., a 55-year-old female recently diagnosed with carcinoma of the large bowel, is admitted to the hospital for an elective colorectal surgical resection; the surgery is expected to last 5 hours. Physical examination reveals a cachectic female with a 20-pound (9.1-kg) weight loss during the previous 3 months (current weight, 132 pounds [59.9 kg]). Increased frequency of bowel movements and chronic fatigue are noted; all other systems are normal. Laboratory data include the following:

Hemoglobin (Hgb), 10.4 g/dL (normal, 12.1–15.3 g/dL; SI units, 104 g/L)
Hematocrit (Hct), 29.7% (normal, 36%–45%; SI units, 0.297)

Prothrombin time (PT), 15 seconds (normal, 10–13 seconds)

Stool guaiac test result is positive. Vital signs are within normal limits. G.B. is taking no medications and has no history of drug allergies. The following orders are written to begin at home on the day before surgery: (a) clear liquid diet; (b) mechanical bowel cleansing with polyethylene glycol–electrolyte lavage solution (CoLYTE®, GoLYTELY®); and (c) neomycin sulfate 1 g and erythromycin 1 g orally (PO) at 1:00, 2:00, and 11:00 PM.

Is the oral route of administration appropriate antibiotic prophylaxis for G.B.?

In general, oral administration of surgical antimicrobial prophylaxis is not recommended because of unreliable or poor absorption of oral agents in the anesthetized bowel. Oral nonabsorbable agents, however, function effectively as GI decontaminants because high intraluminal drug concentrations are sufficient to decrease bacterial counts.[55] The concentration of bacteria in the colon may approach 10^{16} bacteria/μL, and colorectal procedures, such as the one G.B. will undergo, carry a relatively high risk of postoperative infection. Antimicrobial regimens with activity against aerobic and anaerobic bacterial fecal flora (*E. coli* and other Enterobacteriaceae and *B. fragilis*) are effective in preventing postoperative wound infections.[55]

A widely used oral antimicrobial regimen is 1 g each of the nonabsorbable antibiotics neomycin sulfate (for gram-negative aerobes) and erythromycin base (for anaerobes), given 1 day before surgery at the times indicated for G.B.[56] Mechanical bowel cleansing, such as with polyethylene glycol–electrolyte or sodium phosphate lavage solution, precede administration of this regimen; the purpose of bowel purging is to evacuate the colonic contents as completely as possible to decrease colonic bacterial counts. Effective oral prophylaxis includes an aminoglycoside, such as neomycin or kanamycin, plus either erythromycin or metronidazole.[57–59] Thus, the regimen selected for G.B. is highly appropriate.

CASE 63-6, QUESTION 2: The surgical resident has canceled the oral neomycin–erythromycin bowel regimen for G.B. Instead, he orders cefoxitin (Mefoxin®) 2 g IV preoperatively. Is this change in therapy an effective and a rational choice for G.B.?

Numerous parenteral regimens, specifically with agents that possess both aerobic and anaerobic activity, are effective as surgical prophylaxis in colorectal procedures. The second-generation cephalosporins with significant anaerobic activity (eg, cefoxitin) are superior to first-generation cephalosporins, which lack sufficient anaerobic activity.[60] Mechanical bowel preparation with the combination of oral and IV antibiotics is superior to oral or IV agents alone.[56]

Also, the cefoxitin order for G.B. would be unacceptable if the surgery lasts >3.5 hours (the relatively short half-life of cefoxitin could be associated with inadequate antibacterial levels and predispose her to infection).[61] For prolonged procedures (>3 hours) such as anticipated for G.B., an alternative agent with a longer half-life, such as ertapenem, or a second dose of cefoxitin should be considered. Ertapenem has been found to be superior to cefotetan in preventing infection after colorectal surgery.[62] This improved efficacy may be because of the long half-life or broader antibacterial activity.[63] Ertapenem may offer certain advantages as a prophylactic antibiotic, but its use in this indication is discouraged by most clinicians.[12] Although unproved, the potential impact of widespread ertapenem utilization on subsequent carbapenem resistance is of concern.[64] The increased acquisition cost of ertapenem also needs to be considered. Thus, for G.B., the importance of redosing IV regimens with short half-lives in prolonged surgery should be stressed to the resident.

Case 63-6, Question 3: The surgical resident has reconsidered the cefoxitin order and decides to prescribe both the oral and parenteral prophylactic regimens for G.B. Will the combination significantly reduce the rate of postoperative wound infection compared with either regimen administered singly?

Coadministration of an oral regimen followed by a parenteral antibiotic before incision is equivalent or superior to administration of either regimen alone in reducing infection rates.[56],[57],[65] Oral antibiotics, however, have only been evaluated in combination with

mechanical bowel preparation. The optimal agents and regimens as prophylaxis in colorectal surgery remain to be adequately determined. For now, a combination of oral and parenteral antimicrobial prophylaxis with mechanical bowel preparation is recommended for colorectal surgery.[12]

Duration of Administration

CASE 63-7

QUESTION 1: L.G., a 28-year-old male with a history of rheumatic heart disease, has a 12-year history of a heart murmur consistent with mild mitral stenosis and mitral regurgitation. During the past 4 months, his murmur has become much more prominent. In addition, he has experienced severe dyspnea with light physical activity and 3+ pitting edema over both lower legs. Physical examination is notable for coarse rales and an S_3 gallop. For the past 6 weeks, he has been maintained on digoxin and diuretics without significant relief of his SOB. The cardiothoracic surgeon recommends mitral valve replacement and orders the following surgical antibiotic prophylaxis regimen: cefazolin 2 g IV preoperatively, then every 8 hours for 24 hours.

Is cefazolin the most appropriate antimicrobial for L.G.? Why was prophylaxis ordered for only 24 hours?

Although the incidence of postoperative wound infection for cardiothoracic procedures is low (<5%), the devastating consequences of a postoperative endocarditis (after valve replacement) and mediastinitis or sternal osteomyelitis (after sternotomy) warrant antimicrobial prophylaxis.[66–68] Common pathogens associated with cardiothoracic surgery include *S. aureus* and coagulase-negative staphylococci (particularly with hardware placement) (see Table 63-2); based on these potential pathogens, successful prophylactic regimens include cefazolin and cefuroxime. When cefazolin has been compared with cefuroxime or cefamandole, a statistical trend in favor of the second-generation cephalosporins has been noted, and collective wound infection rates were slightly higher in the cefazolin group.[69–71] In contrast, a comparison of prophylactic cefazolin and cefuroxime in patients

having open heart surgery noted a significantly greater incidence of sternal wound infection and mediastinitis in the cefuroxime group.[72] Other studies similarly have not observed improved efficacy with cefuroxime compared with cefazolin.[72–74] Other studies similarly have not observed improved efficacy with cefuroxime compared with cefazolin.[73,74] In conclusion, cefazolin probably is at least as effective as second-generation cephalosporins; therefore, the choice of agent should be based on an institution's antimicrobial susceptibility and cost data. Hospital-specific antimicrobial resistance patterns are especially important in determining the incidence of methicillin-resistant *Staphylococcus aureus* (MRSA) or methicillin-resistant *Staphylococcus epidermidis* (MRSE) SSI rates. Although vancomycin has not been determined to be superior to cefazolin, it is the drug of choice for prophylaxis in patients colonized with MRSA.[12,75] Patients are at higher risk for MRSA carriage if they are frequently hospitalized or have a prolonged hospital stay, are exposed to broad-spectrum antibiotics, are known for comorbid conditions, or have severe underlying illness. The population to be screened for MRSA carriage and undergo decolonization with mupirocin is still being debated but is mostly considered for patients undergoing an orthopedic or a cardiac procedure. Surveillance of susceptibility of *S. aureus* isolated from SSIs should be done if mupirocin is used for decolonization.[76]

Meta-analyses reveal no differences between first- and second-generation cephalosporins or between β-lactams and glycopeptides in the prevention of surgical wound infection.[77,78] Thus, the cefazolin prophylaxis selected for L.G. is acceptable, provided the patient is not colonized with MRSA or MRSE. Additional empiric coverage with an aminoglycoside, a fluoroquinolone, or aztreonam may be considered when gram-negative pathogens are a concern according to local epidemiology and risk factors including hospital admission >48 hours before surgery, diabetes, and ventilator dependency.[12,79]

With regard to duration, the shortest effective prophylactic course of antibiotics should be used (ie, single dose preoperatively or not > 24 hours postoperatively for most procedures).[80] Postoperative doses after wound closure are usually not required and may

increase the risk of resistance. Single-dose prophylaxis given preoperatively, a viable option for many surgical procedures (see Case 63-8, Question 1), is still being evaluated for cardiac procedures.[12,81] In practice, cardiothoracic antimicrobial prophylaxis often is continued up to 24 hours after surgery, as in the case of L.G. No benefit is seen to prolonging prophylaxis to >24 hours, and such use should be discouraged. The duration of antimicrobial prophylaxis ordered for L.G. is appropriate.

CASE 63-8

QUESTION 1: G.J., a 27-year-old female, is admitted to the obstetrics unit at term with her first pregnancy. She is scheduled for a cesarean section because the baby is in a breech presentation. Cefazolin 1 g IV to be administered after the cord is clamped and every 8 hours for 24 hours is ordered.

Is this surgical prophylaxis appropriate or inappropriate?

As noted previously, the shortest effective duration of prophylaxis should be used. In the past, 1- to 5-day antimicrobial regimens were commonly used for cesarean section, but single-dose regimens have been proved to be as effective as these longer regimens.[82] Faro et al[82] demonstrated that a single 2-g dose of cefazolin was superior to either a single 1-g dose or a three-dose, 1-g prophylactic regimen. Others have noted similar results (ie, a single cefazolin dose administered after the umbilical cord is clamped is sufficient in preventing postoperative wound infections in cesarean section).[83–85] Single-dose prophylaxis is less costly and minimizes the development of bacterial resistance.[26] Antibiotic prophylaxis has traditionally been administered after clamping of the umbilical cord to minimize infant drug exposure. This early exposure could theoretically mask the signs of neonatal sepsis and favor the acquisition of resistant organisms. However, administration before initial incision and cord clamping decreases the incidence of maternal infections without adverse consequences to the child.[86] Thus, G.J. should receive a single 2-g dose of cefazolin before incision, without the three additional doses.

Single-dose prophylaxis has been found to be effective in a variety of GI tract, orthopedic, and gynecologic procedures.[51] A single dose of an antibiotic with a short half-life, however, may provide insufficient antimicrobial coverage during a prolonged surgical procedure. Repeated intraoperative dosing or selection of an agent with a longer half-life is recommended when the duration of surgery is long to maintain adequate tissue concentrations throughout the procedure.[12],[52]

Risks of Indiscriminate Antimicrobial Use

Case 63-8, Question 2: G.J. was to receive 24 hours of cefazolin. What are the risks of indiscriminate use of antimicrobials for surgical prophylaxis?

The risks of indiscriminate use of antimicrobials include the potential for adverse effects and superinfection. The administration of any β-lactam agent poses the risk of a hypersensitivity reaction, and many antibiotics, especially broad-spectrum agents, predispose patients to *Clostridioides difficile*–associated disease.[87] The risk of developing this superinfection increases with the duration of antibiotic exposure.[25] Avoiding unnecessary initial and prolonged exposure reduces the risk of this superinfection and its associated complications and could reduce rates of mortality associated with inadequate antibiotic use.[87],[88] In addition, prolonged use of antimicrobials increases the selection of resistant organisms in a given patient that could be spread to other hospitalized patients.[89]

Signs of Surgical Site Infection

CASE 63-9

Question 1: A.L., a 78-year-old female with peripheral venous disease, underwent a left femoral endarterectomy. Three weeks later, she is admitted to the emergency room after developing fever and chills at home, as well as groin redness and swelling. A.L. is diagnosed with left groin abscess that tested

positive for MRSA and antibiotic therapy of IV vancomycin is started. She is then brought to the OR for incision, drainage, and washout of the infected area.

What typical signs of site infection is A.L. presenting? Is she in the typical time course for manifestation of signs of site infection?

The presentation at 3 weeks falls within the typical 30-day time frame for an acute SSI. Abscess formation and deep-seated or indolent infections may take several months before presentation.[4] In addition to redness and swelling, it is pertinent to assess the wound for other warmth, tenderness, localized pain, purulent drainage, and spontaneous wound dehiscence. A surgeon's intervention to open the wound for drainage and debridement is considered diagnostic for infection.[19] Fever, chills, fatigue, and loss of appetite are systemic signs and symptoms that may indicate a more severe or extensive presentation. Complete workup should also include evaluation for deep incisional or organ space involvement.

OPTIMIZING SURGICAL ANTIMICROBIAL PROPHYLAXIS

CASE 63-10

QUESTION 1: As the new infectious disease pharmacist of the institution, you are informed by the infection control team that the antibiotic prophylaxis prescribed by the surgeons is not the same as what is indicated in the institution guidelines.

Which criteria would you want to measure antibiotic prophylaxis prescription performance? What interventions could improve how antibiotics are used in prophylaxis?

Antibiotic control strategies have improved the appropriate use of antimicrobial agents for surgical prophylaxis. Numerous factors including individual knowledge, attitudes, beliefs, and practice; team communication and allocation of responsibilities; and institutional support for promoting and monitoring practice influence antibiotic

prophylaxis measures.[90] Interventions for improvement are focused on education of practitioners, standardization of the ordering, the delivery and the administration processes, and providing feedback on performance as measured by infection rates and compliance with improvements. The SCIP, a national multidisciplinary initiative developed by the Centers for Medicare and Medicaid Services, aims at improving surgical care. Reducing SSIs is one among the targeted goals of this initiative.[91] Prophylactic antimicrobial received within 1 hour of surgical incision, prophylactic antimicrobial consistent with published guidelines, and prophylactic antimicrobial discontinued within 24 hours of surgery end time are three performance measures included in this quality improvement process. The first two, antibiotic timing of administration and appropriate antibiotic selection, are associated with a decrease in the SSI rate.[22]

Smaller scale projects have also been successful in improving antibiotic use and decreasing infection rates. A multidisciplinary team generated electronic quick orders allowing for a computer-enhanced decision-making process and developed an antibiotic administration protocol. Appropriate selection of antibiotics increased from 78% to 94%, timely administration improved from 51% to 98%, and clean wound infection rate decreased from 2.7% to 1.4%.[92]

In collaboration with other health care providers, pharmacists should be responsible for optimizing the timing, choice, and duration of antimicrobial surgical prophylaxis. Education of surgical, anesthesia, and nursing staff, supported by hospital policy changes initiated by pharmacists, improved appropriate timing from 68% to 97% and resulted in significant cost avoidance.[93] Postdischarge surveillance is also critical in reducing SSIs.[94]

Vaccinations

Molly G. Minze and Katie D. Ellis

CORE PRINCIPLES		CHAPTER CASES
GENERAL VACCINE PRINCIPLES		
1	Adverse effects: Immunization adverse effects are in part dependent upon the type of vaccine preparation used. Adverse effects from live attenuated vaccines mimic the disease but are less severe and occur 7 to 10 days postvaccination. Inactivated (killed whole virus) vaccination adverse effects include soreness at the site of administration within 24 hours of the vaccination. Vaccination adverse effects are significantly less severe than is the disease itself.	**Case 64-1 (Question 1)**
2	Immunization schedules: Recommended immunization schedules	**Case 64-2 (Question 1)**

	are designed to optimize immune response, standardize regimens, and enhance immunization rates. Birth to 18 years and adult immunization schedules are reviewed and updated annually.	
3	Catch-up immunization schedules: To catch up within an immunization series, it is not necessary to restart from the first dose of the schedule. A delay in receiving subsequent doses does not interfere with final immunity gained from the vaccination.	**Case 64-3 (Question 1)**
	INACTIVATED VACCINES	
1	Hepatitis B: Hepatitis B vaccination is effective for both pre-exposure and postexposure prophylaxis. To prevent vertical transmission to an infant from a mother, it is key to provide vaccination within 12 hours of birth along with hepatitis B immunoglobulin for those mothers who test hepatitis B–positive.	**Case 64-4 (Question 1)**
2	Hepatitis B: Rates of hepatitis B are low in children and adolescents. Over half of acute hepatitis B infections occur in patients ages 30 to 49. Hepatitis B vaccination is recommended for adults who participate in high-risk behaviors, those in close contact with the infected persons, and patients with chronic liver disease.	**Case 64-4 (Question 2)**
3	Hepatitis A: Hepatitis A immunization is targeted toward toddlers with the aim of	**Case 64-5 (Question 1)**

	preventing transmission to adolescents and adults. It is also recommended for patients traveling to countries with high or intermediate endemic hepatitis A.	
4	Diphtheria, tetanus, and acellular pertussis/pertussis booster: Waning immunity against pertussis has resulted in outbreaks of pertussis in the United States. Adolescents and adults, particularly those with close contact with young infants, should receive a single dose of pertussis booster vaccine.	**Case 64-6 (Question 1)**
5	*Haemophilus influenzae b*: Immunization recommendations for *H. influenzae* type b are age dependent. The older an infant is at presentation, the fewer the doses needed to elicit a response. A single vaccine dose may be considered in children and adults with underlying diseases that place them a risk for infection.	**Case 64-7 (Question 1)**
6	Polio: Inactivated polio vaccine is recommended over the oral attenuated vaccine for polio vaccination in the United States because inactivated vaccine is associated with a lower incidence of vaccine-associated paralytic polio.	**Case 64-8 (Question 1)**
7	Polio: Routine vaccination of adults against polio with inactivated poliovirus vaccine is not recommended unless individuals plan travel to endemic areas.	**Case 64-9 (Question 1)**

	Oral polio vaccine may be considered only in unique situations.	
8	Meningococcal: Vaccination is recommended within populations at increased risk for contracting *Neisseria meningitidis*, including travelers to endemic areas, patients with specific immunodeficiencies, functional/anatomic asplenia, laboratory personnel dealing with meningococcus, and college students.	**Case 64-10 (Question 1)**
9	Human papillomavirus: This two- or three-dose vaccination series is recommended for adolescent patients for the prevention of anogenital cancers, anogenital warts, and head and neck cancers, in males and females. It is also recommended for the prevention of cervical cancers in females.	**Case 64-11 (Question 1)**
10	Pneumococcus: *Streptococcus pneumoniae* mostly affects young children and the elderly. The conjugate vaccines protect against 80% (pneumococcal conjugate vaccine [PCV 7]) and 90% (PCV 13) of infectious strains that cause disease in children younger than 6 years old.	**Case 64-12 (Question 1)**
11	Pneumococcus: The polysaccharide vaccine does not elicit immune response in children younger than 2 years old, and protects against 23	**Case 64-12 (Question 2)**

	strains of *S. pneumoniae* that typically cause adult disease.	
12	Influenza: Vaccination is recommended for anyone older than 6 months of age who does not have a current contraindication. The inactivated vaccine is delivered intramuscularly or intradermally, whereas the live attenuated vaccine is delivered as a nasal spray formulation.	**Case 64-13 (Question 1)**
LIVE ATTENUATED VACCINES		
1	Rotavirus: Infants vaccinated with the rotavirus vaccine shed the virus in the feces after immunization; however, the risk of transmission to an immunocompromised contact is relatively low with appropriate precautions.	**Case 64-14 (Question 1)**
2	Measles, mumps, rubella (MMR): Parents are fearful of the risk of autism that has been falsely associated with the MMR vaccine. Pharmacists must provide counseling to overcome parental fears and ensure protection against measles.	**Case 64-15 (Question 1)**
3	Varicella: Postexposure vaccination with the varicella vaccine is recommended within 5 days of exposure for those unvaccinated or who have not received a second dose of vaccine.	**Case 64-16 (Question 1)**
4	Varicella: Herpes zoster vaccination is	**Case 64-16 (Question 2)**

	recommended in adults older than 50 years of age to prevent reactivation of previously acquired wild-type varicella zoster infections.	
COVID-19 VACCINES		
1	COVID-19: COVID 19 vaccination is recommended for people 6 months and older.	**Case 64-17 (Question 1)**
IMMUNIZATION PRACTICES		
1	Vaccine administration: Intramuscular vaccinations are administered at a 90-degree angle into the muscle using a 1-inch needle. Subcutaneous vaccinations are administered at a 45-degree angle into the subcutaneous tissue by pinching this tissue up to prevent insertion into the muscle. When multiple injections are given at the same site, separate each injection by 1 inch.	**Case 64-18 (Question 1)**
2	Advocacy and establishing services: Pharmacists have an important role as immunization advocates to positively increase immunization rates. Pharmacist immunization training is widespread throughout the United States, but pharmacists must adhere to guidelines and principles established by their state Pharmacy Practice Act when administering immunizations to patients.	**Case 64-19 (Question 1)**

INTRODUCTION

The use of immunizations to control common infectious diseases is a major public health achievement. Children, adolescents, and adults are now routinely immunized against 17 infectious diseases.[1] Immunization rates are high overall and have remained stable in the United States, with >80% of children age 3 years receiving all the recommended vaccines.[2] As a result, low levels of vaccine-preventable diseases are occurring. Rates of immunization for adults against influenza and pneumococcus range from 23% to 45%, with higher coverage for individuals older than age 65 years.[3] Unfortunately, despite the overall high rates of immunization coverage, disparities still exist in vaccination coverage for the socioeconomically disadvantaged and by ethnicity.[2] Clearly, there is room for improvement and an opportunity for all health professionals to have an impact.

The need for timely immunization administration is key to preventing disease resurgences.[4] As the incidence of vaccine-preventable disease continues to decrease, patients are becoming less aware of the significance and severity of the diseases that could be prevented.[5–9] This, along with parental concerns regarding vaccine safety, may jeopardize previous vaccination achievements.[7,8] Health care providers play a vital role in clarifying misconceptions and educating parents and other health professionals about the importance of proper and complete immunizations.[7] Any contact with a patient represents an opportunity to promote immunization, and thus every medication history should include a review of immunization status to detect any deficiencies.[9]

VACCINE PRINCIPLES

General Principles

The principle of vaccination against disease is that the introduction of a small amount of the pathogen to the body produces protective immunologic memory (active immunity) and, if the pathogen is reintroduced at a later date, a greater immunologic response is elicited but without inducing disease.[10] The ideal vaccine would present a nonvirulent form of a pathogen that produces a strong immunologic response once in the body.[11]

Vaccine types include live attenuated, killed (inactivated) whole organism, subcellular/subunit, and DNA-based vaccines[11] (see **Table 64-1** for a listing of common vaccines and their formulation type). In addition, recent COVID-19 vaccine types include messenger ribonucleic acid (mRNA), adenovirus, and subunit protein vaccines.[12–15] Live attenuated vaccines contain weakened or inactivated forms of the pathogen, which causes replication within the host and ultimately elicits antibody- and cell-mediated immunity within the body via B-cell and T-cell responses.[11,12,16,17] Live vaccine administration produces a mild, typically asymptomatic infection at the time of vaccination followed by long-lived immunity from a single immunization.[18,19]

Table 64-1
Vaccine Overview

	Vaccines	Recommended Regimens	Comment
Diphtheria, tetanus, pertussis (inactivated; intramuscular)	<7 years: DTaP, DT ≥7 years: Tdap, Td	DTaP: 2, 4, 6, 15–18 months; booster at 4–6 years Tdap routine vaccination: 11–12 years Td or Tdap booster: Every 10 years	Minimum age 6 weeks; fourth dose can be administered at 12 months of age if at least 6 months since third dose Minimum age 10 years (Boostrix® and Adacel®)
Haemophilus influenzae type b (Hib; inactivated; intramuscular)	Hib	2, 4, 6, 12–15 months	Minimum age 6 weeks If PRP-OMP (PedvaxHIB®) at 2 and 4 months, no 6-month dose indicated (2, 4, and 12–15 months) PRP-T (ActHIB® and Hiberix®) is a four-dose series.
Hepatitis B (inactivated; intramuscular)	Hep B	Birth, 1–2 months, 6–18 months	Monovalent vaccine to be administered for any doses before 6 weeks Administer birth dose within 12 hours if HBsAg-positive mother Final dose should not be given before 6 months of age.
Hepatitis A (inactivated; intramuscular)	Hep A	Two doses 6 months apart	Minimum age 12 months
Human papillomavirus vaccine (inactivated; intramuscular)	HPV9	Two doses 9–14 years Three doses 15–26 years Second dose 1–2 months after first Third dose 6 months after first	Administer before sexual activity.
Influenza (IIV4 = inactivated; intramuscular) (LAIV 4 = live attenuated; intranasal)	IIV4, LAIV4	Annually Two doses 4 weeks apart at first annual vaccination	Minimum age IIV4 6 months Minimum age LAIV4 2 years Two doses required for patients ages 6 months–8 years at first annual vaccination
Measles, mumps, rubella (MMR; live attenuated; subcutaneous)	MMR	12–15 months; repeat dose 4–6 years	Minimum age 12 months; second dose may be administered as early as 4 weeks after previous dose.
Meningococcal serogroup A, C, W, Y vaccination (MCV = inactivated; intramuscular)	MCV4 (Menactra®, Menveo®, MenQuadfi®)	Two-dose series: 11–12 years, 16 years	Minimum age for Menveo® = 8 weeks; Menactra® = 9 months; MenQuadfi® = 2 years First-year college students not previously vaccinated at age 16 or older: one dose Menactra®, Menveo®, or MenQuadfi®
Meningococcal serogroup B vaccination (inactivated; intramuscular)	MenB-4C, Bexsero®; MenB-FHbp, Trumenba®	If not at increased risk: Bexsero® = two-dose series 1 month apart Trumenba® = two-dose series 6 months apart	In special situations in patients at increased risk, Trumenba® is a three-dose series. The two vaccines are not interchangeable.

	Vaccines	Recommended Regimens	Comment
Pneumococcal (inactivated polysaccharide; usually intramuscular, but subcutaneous ok) Pneumococcal (conjugate; intramuscular)	PCV 13, 15, 20 PPSV 23	2, 4, 6, 12–15 months If decided, 1 PCV 13 dose one dose ≥65 years PCV 20 If PCV 15 used, follow with PPSV 23 1 year later	PCV minimum age 6 weeks PPSV minimum age 2 years Administer PCV 13 dose before PPSV 23.
Polio (inactivated; usually intramuscular, but subcutaneous ok)	IPV	2, 4, 6–18 months	IPV minimum age 6 weeks If four or more doses given before 4 years of age, repeat booster at 4–6 years. Final dose should be after fourth birthday and at least 6 months after previous dose.
Rotavirus (live attenuated; oral)	RV1 RV5	2, 4 months 2, 4, 6 months	Initial dose: minimum age 6 weeks, maximum age 14 weeks 6 days Final dose: maximum age 8 months Rotarix® (RV1): 6-month dose not indicated
Varicella (live attenuated; subcutaneous)	VZV	12–15 months; repeat dose at 4–6 years	Minimum age 12 months; second dose may be administered as early as 3 months from previous dose.
Zoster (recombinant; intramuscular)	RZV	50 years of age	Two-dose series 2–6 months apart, minimum interval 4 weeks. Delay RZV until after pregnancy.

HBsAG positive +, hepatitis B surface antigen positive; PRP-OMP, PedvaxHIB or Comvax™ (Hep B-Hib).

Advisory Committee on Immunization Practices recommended immunization schedule for adults aged 19 years or older—Unites States, 2021. *MMWR Morb Mortality Wkly Rep*. 2022;71:229–233.

Killed whole organism and subcellular/subunit vaccines do not replicate within the host, nor can they revert to pathogenicity, but they often require adjuvants and/or multiple doses to increase the duration of immune response to the antigen.[11,16] Because the organisms in whole-pathogen vaccines are inactivated (killed), their effectiveness may be impaired by circulating antibodies, maternal antibodies (in infants), or concomitant infections. Toxoids are a specific kind of inactivated vaccine formed by modifying a biologic toxin (eg, diphtheria and tetanus), usually by mixing it with formaldehyde.

Subunit vaccines contain either a protein or polysaccharide antigen within the vaccine and elicit less reaction than do whole-pathogen vaccines; thus, immune responses are weaker and require multiple doses similar to that of inactivated vaccines.[11] Conjugate subunit vaccines, consisting of a polysaccharide protein conjugate where the protein is the antigenic toxin, produce improved immune responses because of B-cell activation by the polysaccharide component and T-cell activation by the protein component. Recombinant vaccines available include hepatitis B, human papillomavirus (HPV), recombinant and live influenza, live typhoid vaccine, meningococcal serogroup B vaccine, and live rotavirus.[20]

mRNA vaccines use nonviral vector nucleic acid–based genetic encoding in a protein to be incorporated and expressed at the level of the cell membrane, which causes a coordinated immune response in the host.[21],[22] These vaccines express a specific antigen to produce a directed humoral and cell-mediated response.[23] mRNA vaccines available at this time are for COVID-19.

Adenovirus vaccines are viral vector vaccines that use a weakened, nonvirulent, nonreplicating virus to deliver genetic material to encode proteins for specific antigen production in the host cells.[22],[24] These vaccines are in development for COVID-19, Ebola, human immunodeficiency virus (HIV), tuberculosis, and malaria.[22] A limitation of these vaccines is if the host has any preexisting immunity to the viral vector.[22]

Adverse Effects

CASE 64-1

Question 1: H.P. is a 38-year-old female concerned about the side effects of the annual influenza "shot."

What information can be provided regarding expected adverse effects for H.P.?

Vaccine adverse events are classified as local, systemic, or allergic.[1] Adverse reactions to inactivated vaccines include pain at the injection site and fever within 48 to 72 hours of administration.[25–27] In contrast, adverse effects from live attenuated vaccines occur 7 to 10 days after immunization, after the virus has replicated and the immune system has responded. Adverse reactions to live attenuated vaccines mimic the symptoms of disease. Transient rash occurs in 5% of patients receiving measles, mumps, rubella (MMR) immunizations, and a mild varicella-like rash (median of five lesions) occurs in <5% of patients receiving the varicella vaccine. Syncope, usually occurring within 30 minutes of immunization, has been reported, with 70% of syncopal episodes occurring within 15 minutes of immunization, and occurs more commonly in female patients and adolescents.

Although anaphylactic reactions to vaccines are rare, an allergic reaction may occur as a result of specific allergy to the vaccine itself or to trace components in the vaccine (eg, preservatives, antibiotics).[27] The best practice to prevent allergic reactions is through screening and obtaining a history of any previous allergic reactions to vaccinations, vaccine components, or hypersensitivities.[1] Patients with egg allergy can receive vaccines produced in chick-embryo-fibroblast tissue culture (eg, MMR) because the risk factor for serious reaction to these vaccines in egg-allergic individuals is very low.[28–31] MMR should be used cautiously in individuals with a history of a severe reaction to gelatin, which is a stabilizer in the MMR vaccine. Trace amounts of streptomycin, bacitracin, and neomycin are present in oral polio virus vaccine, inactivated polio vaccine (IPV), and MMR; therefore, these vaccines should not be administered to individuals with a history of an anaphylactic reaction to these antibiotics.[31]

Overall, vaccinations are safe, especially when compared with the risks of the diseases that these vaccines prevent, and the safety of immunizations are scrutinized continually.[31–33] In response to concerns about vaccine safety, the National Vaccine Injury Compensation Act mandated an ongoing review of evidence

regarding the possible adverse effects of vaccines and established a no-fault injury compensation program for selected vaccines.

Contraindications

Misconceptions about contraindications and precautions for immunization often result in missed opportunities to provide needed immunizations.[1,34] Acute, severe febrile illness; history of anaphylaxis to the vaccine or vaccine components; and history of a severe reaction to an immunization are clear contraindications to immunizations. Immunizations, however, should not be delayed in a patient who has a minor illness (eg, upper respiratory tract infection, otitis media, diarrhea), even in the presence of a low-grade fever. A family history of seizures, allergies, and sudden infant death syndrome are not contraindications for immunizations. Immunization of a patient with a history of anaphylaxis to a vaccine or vaccine component should be withheld until he or she has undergone desensitization. Preterm infants should begin to receive routine immunizations based on their chronologic age for all vaccines, although initiation of the hepatitis B series should begin at age 1 month.

Allergic reaction to previous exposure to vaccine components, immunosuppression (eg, immunosuppressive therapy, immunodeficiencies), encephalopathy, recent administration of blood products, and pregnancy (although the risk in pregnancy is largely theoretic) are contraindications to live attenuated virus or live bacterial vaccines. Pooled blood products (eg, immunoglobulins [Igs], packed red blood cells, platelet transfusions) can impair the immune response to a live vaccine because these products contain antibodies that can prevent one's immune system from mounting an adequate response.[1] The impairment of an immune response to an immunization varies, depending on the type and amount of blood product administered, and immunizations may need to be delayed for up to 12 months if pooled blood products have been administered recently.[1] With any question about immune response, antibody titers

can be obtained to determine whether a patient needs to be reimmunized.

GUIDELINES

Schedule for Immunizations

CASE 64-2

QUESTION 1: K.C., a 2-month-old female, is brought to the clinic for a scheduled well-baby visit. K.C.'s mother inquires about immunizations for her daughter.

What are the current recommendations for immunizing pediatric patients? When should these immunizations be given to K.C.?

The goal of immunization is to prevent specific infectious diseases and their sequelae. For maximal effectiveness, a vaccine must be administered to the susceptible population before anyone has been exposed to the pathogen. The age at which immunizations are administered to specific individuals depends on several factors (eg, age-specific risks of the disease, risks of complications, presence of maternal antibodies transferred through the placenta, maturity of the immune system). Usually, immunizations are administered at the youngest age that the child is able to develop an adequate antibody response.

The recommended childhood and adolescent immunization schedules are reviewed annually by the Advisory Committee on Immunization Practice (ACIP) and the American Academy of Pediatrics (AAP), and supported by the American Academy of Family Physicians (AAFP), the American College of Obstetricians and Gynecologists (ACOG), and published within the Morbidity and Mortality Weekly Report [35,36] and are available online (http://www.cdc.gov/vaccines/schedules). A partial summary of vaccination schedules is included in Table 64-1, but the reader is referred to the online publication of immunization schedules for a

more complete listing of the most current recommendations. The minimal immunization requirements for entry into public schools and day care centers vary with each state and the departments of health of individual states need to be consulted for these guidelines. The ACIP reviews the adult immunization schedule annually as supported by the American College of Physicians (ACP), AAFP, and the American College of Nurse-Midwives (ACNM) and published within the Annals of Internal Medicine and the Morbidity and Mortality Weekly Report [37,38] (available online at https://www.cdc.gov/vaccines/schedules/index.html). The respective schedules for children and adults should be reviewed annually, and the policies and procedures revised to ensure compliance.

A review of the childhood immunization schedule reveals that the recommended vaccines to be administered at 2 months of age include diphtheria, tetanus, and acellular pertussis (DTaP), IPV, *Haemophilus influenzae* type b (Hib), pneumococcal conjugate vaccine (PCV 13), and rotavirus vaccine. A second dose of the hepatitis B (Hep B) vaccine should also be administered if the first dose was given at birth. If Hep B vaccine was not given to K.C. at birth, the first dose should be given today, then repeated 4 weeks later, and again at 6 months (see Case 64-4, Question 1).

CASE 64-3

QUESTION 1: K.C.'s mother also mentions that she personally received two doses of an HPV vaccine series. Her physician asked her to receive a third dose in December, and it is now March.

Does K.C.'s mother need to restart the vaccination series for HPV?

Immunization schedules can be adjusted to meet individual needs and may begin at any time of the year. Vaccines should not be administered at time intervals shorter than those recommended to allow for maximal immune responses before the administration of subsequent doses.[1] A "catch-up" schedule for immunizations of children and adolescents who begin their immunizations late or who are >1 month behind schedule in their immunizations and

recommendations for minimal intervals between doses for the administration of various vaccines can be implemented.[1,35,36] It is not necessary for adults who delay administration of a subsequent dose of an immunization series to restart the vaccination series. An interruption or a delay in the recommended schedule does not interfere with the final immunity gained.

Alternative immunization recommendations are available for patients with altered immunocompetence to ensure protection from vaccine-associated disease, yet prevent adverse effects or acquiring disease from the vaccine itself in the case of live attenuated vaccines.[1,37–39] As an adult, K.C.'s mother should receive a third dose of HPV vaccine as soon as possible, but she does not need to restart the whole series.

INACTIVATED VACCINES

Hepatitis B

CASE 64-4

QUESTION 1: A.G. is an infant (weight 4.63 pounds [2.1 kg]) born to a mother in whom the hepatitis B surface antigen (HBsAg) status is unknown.

How should A.G. be managed?

Hepatitis B virus (HBV) can be transmitted via exposure to contaminated blood (eg, blood products or medical instruments, nonsterilized needles used in intravenous drug abuse, or tattooing), exposure to body fluids (eg, sexual intercourse), and transplacentally from an HBsAg-positive mother.[40] The prevention of HBV maternal transmission to an infant is essential because acute disease can progress to a chronic carrier state, which can lead to chronic liver disease and primary hepatocellular carcinoma. Children acquiring HBV infection before 5 years of age are at an especially high risk for

developing chronic infection.[40] All pregnant females should be tested for HBsAg, and HBsAg-positive pregnant females should be tested for hepatitis B virus deoxyribonucleic acid (HBV DNA). Infants born to HBsAg-positive mothers should receive their first vaccine dose in addition to hepatitis B immune globulin (HBIG) within 12 hours of birth, regardless of birth weight, to prevent vertical transmission.[41] When combined, HBIG plus HBV vaccine are 99% effective in preventing acute and chronic infection in infants born to HBsAg-positive mothers.[41] If the mother's HBsAg status is unknown, the infant should be also immunized with the Hep B vaccine within 12 hours of birth regardless of birth weight. For infants weighing <4.41 pounds (2 kg), HBIG should also be administered within 12 hours of birth. The mother's HBsAg status should be determined at the first opportunity. If the mother is HBsAg positive, HBIG should be administered to infants weighing ≥4.41 pounds (2 kg) as soon as possible, but no later than day 7 of life.[41] Medically stable infants weighing ≥4.41 pounds (2 kg) born to HBsAg-negative mothers should begin their immunization series within 24 hours of birth. Infants weighing <4.41 pounds (2 kg) and born to HBsAg-negative mothers should have their first vaccine dose delayed to the time of hospital discharge or age 1 month (even if weight is still <4.41 pounds [2 kg]). In all situations, subsequent vaccine doses should be administered at age 1 to 2 months and again at age 6 months. All unimmunized children should receive HBV vaccine as soon as they are identified.[41]

A.G. should receive Hep B vaccine within 12 hours of birth and the mother's status should be determined. If her mother is found to be HBsAg positive, HBIG should also be administered within 7 days of birth. A.G. can receive her subsequent doses of HBV vaccine according to the childhood immunization schedule. Three Hep B vaccines are currently available for use in the United States. Recombivax-HB® and Engerix-B® are yeast-derived recombinant vaccines administered as a three-dose series.[41,42] Either formulation can be used because the immune response from an immunization series using different vaccines is comparable to that of a full series using a single vaccine.[1,43] Heplisav-B® (Hep B CpG) is a two-dose

series indicated for adults ages 18 years and older as an option for unvaccinated or incompletely vaccinated individuals. The two-dose series only applies when both doses consist of Hep B CpG, and the doses should be administered 4 weeks apart. Revaccination is not recommended in patients with a normal immune system who were vaccinated as infants, children, adolescents, or adults. However, if anti-HBs <10 mIU/mL, revaccination is recommended for infants born to HBsAg-positive mothers, patients on hemodialysis, and other immunocompromised persons.[35,36]

CASE 64-4, QUESTION 2: A.G.'s mother (age 17 years) has not herself been immunized against hepatitis B. Should she begin receiving the Hep B series as well?

Despite a decline in hepatitis B infections in the United States after universal childhood immunization, more than a million adults are living with chronic hepatitis B infection. The highest incidence of acute hepatitis B in the United States occurs in adults ages 30 to 49 years, the majority of which occur in individuals with high-risk behaviors including multiple sexual partners, anal intercourse, and injectable drug abuse.[42] Individuals who have close contact with patients infected with hepatitis B, including health care workers, are also at risk of infection.[42] Children and adolescents not vaccinated during infancy should be given a three-dose series of intramuscular (IM) injections. Hep B vaccine is now universally recommended for all adults ages 19 through 59 years, and a two-, three-, or four-dose series should be recommended for routine vaccination. For patients ages 60 and older at risk for hepatitis B infection, a two- or three-dose series should be recommended. Patients ages 60 and older considered at risk include patients with chronic liver disease, HIV infection, sexual exposure risk, current or recent injection drug use, percutaneous or mucosal risk for exposure to blood, incarcerated persons, or those who travel in countries with high or intermediate endemic hepatitis B. Anyone age 60 or older who does not meet the recommendations based on risk may still receive hepatitis B

vaccination.[37,38] Antibody screening after immunization is only recommended in high-risk groups in whom future clinical management may depend on knowledge of immune status (eg, health care workers). Recommendations for serologic testing and revaccination and postexposure prophylaxis for such situations are available.[42] Patients on dialysis and other immunocompromised patients may require a fourth dose if the anti-HBs level is <10 mIU/mL 2 months after the third dose.[42]

A.G.'s mother should begin a three-dose series of Hep B vaccine. Monovalent vaccines are preferred for the initial vaccination; however, combination vaccines may be used[1,43] (see **Table 64-2**). Combination vaccines should not be used for infants younger than age 6 weeks; therefore, only single-antigen doses should be used for birth doses.[41] Of note, Heplisav-B® is not recommended during pregnancy owing to lack of safety data.[37,38]

Table 64-2
Combination Vaccines

Combination Vaccine[a]	Antigens[b]	Age Indicated	Regimen
Kinrix®	DTaP-IPV	4–6 years	Only for fourth dose of IPV and fifth dose of DTaP
Quadracel®	DTaP-IPV	4–6 years	Only for fourth dose of IPV and fifth dose of DTaP
Pediarix®[c]	DTaP-Hep B-IPV	6 weeks–<7 years	2, 4, 6 months
Pentacel®	DTaP-IPV-Hib	6 weeks–4 years	2, 4, 6, 15–18 months An extra monovalent IPV recommended for IPV at 4–6 years (total, five doses)
ProQuad®[d]	MMR-V	12 months–12 years	12–15 months, 4–6 years
Twinrix®	Hep A-Hep B	18 years+	0, 1, 6 months
Vaxelis®	DTaP-Hep B IPV-Hib	6 weeks–5 years	2, 4, 6 months

DTaP, diphtheria, tetanus, and acellular pertussis; Hep A hepatitis A; Hep B, hepatitis B; Hib, *Haemophilus influenzae* type b; IPV, inactivated poliovirus vaccine; MMR, measles, mumps, and rubella vaccine; V, varicella vaccine.

[a]Vaccine interchangeability: If combination and single-antigen vaccines are used to complete an immunization series, it is preferred to use products from the same manufacturer. Immunogenicity of vaccine antigens between different manufacturers is unknown.

[b]Extra antigens: Administration of extra antigens using combination vaccines should be avoided. Availability of monovalent vaccines should be provided to avoid giving extra antigens and increase risk of adverse effects, particularly for inactivated vaccines which are reactogenic (eg, DTaP vaccine).

[c]Hepatitis B: Combination vaccines not recommended for hepatitis B birth doses (<6 weeks).

[d]ProQuad®: MMRV may be associated with an increased risk of febrile seizures when used at age 12 to 47 months. The use of MMR is preferred during this time.

Use of combination measles, mumps, rubella and varicella vaccine: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep.* 2010;59(RR-3):1–12.

Hepatitis A

CASE 64-5

Question 1: A mother presents with her 2-year-old to her pediatrician for a well-child visit. Her pediatrician encourages her to have her child immunized against hepatitis A.

What are the differences between hepatitis B and hepatitis A infections, and what are the immunization recommendations?

Hepatitis A infection can present as either an acute or a chronic illness, but it is often asymptomatic in infants and young children. However, infections in older children and adults typically present with fever, malaise, anorexia, nausea, abdominal discomfort, and jaundice.[44] Clinical illness usually lasts 1 to 2 months, but it may be relapsing and can last up to 6 months. In 2017, adults ages 30 to 39 years had the highest reported incidence of hepatitis A.[45] Among all reported cases, the most common source of infection is household or sexual contact, followed by day care attendance or employment, international travel, and food or waterborne outbreaks. Asymptomatic children serve as a source of infection, especially for household or other close contacts.[45]

Vaccination programs targeting toddlers and young children are important because children are often asymptomatic and unwittingly transmit the virus to adolescents and adults. In addition, data suggest a “herd effect” when vaccination of children is widespread (ie, large population immunization programs indirectly protect those who are not immunized because the risk of being exposed to an infected individual is reduced).[46] A program aimed exclusively at toddlers in an endemic area reduced the prevalence of hepatitis A by >90%, not only in the 2- to 4-year-old vaccine recipients but in all age groups.[46]

There are two hepatitis A (Hep A) vaccines on the market, Havrix® and Vaqta®, each with adult and pediatric formulations. The pediatric formulations of the vaccine for routine vaccination are indicated for infants 12 months and older, and contain half the antigen of the adult formulations.[44] Vaccination involves a two-dose regimen, with the second dose to be administered 6 to 18 months after the initial dose, depending on the formulation (see Table 64-1). Two doses of hepatitis A vaccine should be administered to all children ages 2 to 18 years who have not previously received the Hep A vaccine. All patients age 1 year and older with HIV should be vaccinated. Persons with chronic liver disease, pregnant patients who are identified to be at risk for infection during pregnancy, or patients at risk for having a severe outcome from Hep A infection should be vaccinated. Vaccination during hepatitis A outbreaks of persons ages 1 year and older who are at risk for Hep A infection (eg, persons who use injection or noninjection drugs [ie, all those who use illegal drugs], persons experiencing homelessness, or men who have sex with men [MSM]) or who are at risk for severe disease from HAV (eg, persons with chronic liver disease or who are infected with HIV) is recommended. Additional groups of individuals who should be vaccinated include people in settings providing services to adults in which a high proportion of persons have risk factors for Hep A infection (eg, health care settings with a focus on those who use injection or noninjection drugs, group homes, and nonresidential day care facilities for developmentally disabled persons). Vaccination of persons who receive blood products for clotting disorders is no

longer recommended.[47] Adults for whom Hep A vaccination is recommended include those with high-risk behaviors, individuals who work with hepatitis A virus–infected primates or in a hepatitis A research laboratory setting, patients with chronic liver disease, and those traveling to areas where hepatitis A is endemic.[37],[38],[47] A combination vaccine containing both Hep A and Hep B is available and indicated in individuals older than age 18 years on a three-dose schedule (see Table 64-2).

Diphtheria, Tetanus, Pertussis Vaccines

CASE 64-6

Question 1: N.R. is a nurse who cares for children in a hospital setting. She calls with confusion regarding the need for her to receive a "pertussis booster." She indicates that she received her DTaP immunization series as recommended during childhood and her last tetanus shot was 3 years ago.

Should N.R. receive the pertussis booster (Tdap)?

Pertussis ("whooping cough"), an infectious disease caused by *Bordetella pertussis*, is characterized by a paroxysmal cough with a whoop-like, high-pitched inspiratory noise; vomiting; and lymphocytosis.[48] It is a highly communicable infection, which can affect 90% of infants and young children in nonimmunized households, and can be associated with serious sequelae, particularly in young infants. An estimated 0.3% to 14% of patients with pertussis experience encephalopathy, 0.6% to 2% have permanent neurologic damage, and about 0.1% to 4% die.[49] This serious childhood infection has been mitigated by the availability of an acellular pertussis vaccine (aP), which commonly is administered in combination with diphtheria (D) and tetanus (T) vaccines (DTaP). A primary series of four doses of DTaP is recommended at 2, 4, 6, and 15 to 18 months followed by a booster dose at school entry or 4 to 6 years of age.[35],[50] The efficacy of the DTaP vaccines against pertussis after primary immunization (three doses) is >80%.[50] Protection increases to 90% after the last booster (age 4–6 years)

and then decreases during the next 12 years, after which protection is minimal.[51,52]

Historically, DTaP vaccines contained whole-cell pertussis antigens. However, because of concerns regarding adverse effects, products currently available contain acellular pertussis antigens (see Table 64-1). Despite a more favorable adverse effect profile, the DTaP vaccine is contraindicated in anyone experiencing an anaphylactic reaction or encephalopathy within 7 days of immunization with DTaP when these symptoms cannot be attributed to another cause.[50] In addition, careful consideration of subsequent doses should be given to infants experiencing a temperature of 105 °F (40.56 °C; not resulting from another cause) or persistent, inconsolable crying lasting >3 hours within 48 hours of the administration of a pertussis-containing vaccine.[50] The pertussis component of the DTaP vaccine should be eliminated (ie, continue vaccination with DT) in any child experiencing collapse or a hypotonic–hyporesponsive episode. If an evolving neurologic disorder is present, pertussis immunization should be deferred until the neurologic problem has been fully evaluated. Preexisting, stable neurologic conditions (eg, well-controlled seizures) are not contraindications because the benefits of pertussis immunization outweigh the risks. A family history of seizures or other central nervous system (CNS) disorders is not a contraindication to vaccination.[51]

Two DTaP vaccines (Infanrix® and Daptacel®) are approved for the primary vaccination series. Combination vaccines may also be used; however, their use for primary vaccination is product dependent (Table 64-2).[48] If possible, the same DTaP product should be used for all five doses because the immunity, safety, and efficacy associated with the interchanging of different DTaP vaccines are unknown.[1,35] If the product information is unknown or unavailable from prior vaccinations, however, any licensed DTaP vaccine can be used to complete the vaccination series.[1,35]

Despite the availability of an effective vaccine and a high rate of vaccine coverage, pertussis continues to cause morbidity in patients of all ages in the United States.[48] Decreased immunity in

adolescents and adults is believed to contribute to this problem. About 12% of adult patients with a cough lasting >2 weeks have pertussis.[53] Although the illness is typically mild in adults and adolescents, they serve as a source of transmission to unprotected infants. This has led to the development and recommendation of acellular pertussis booster vaccines for adolescents and adults with a tetanus and diphtheria toxoid and acellular pertussis vaccine (Tdap).[1,35,54] (Note the designation as *dap* compared with *DaP* for primary vaccines.)

All pregnant females should receive one dose of Tdap during each pregnancy, irrespective of their history of receiving the vaccine.[54] Tdap should be administered at 27 to 36 weeks' gestation, preferably during the earlier part of this period, although it may be administered at any time during the pregnancy. The routine use of a single dose of pertussis booster (Tdap) is recommended for adolescents at ages 11 to 18 years. This population should receive a single dose of Tdap, preferably at a preventive care visit at ages 11 to 12 years. To ensure continued protection against tetanus and diphtheria, one booster dose of either Td or Tdap should be administered every 10 years throughout life. Regardless of the interval since their last tetanus or diphtheria toxoid–containing vaccine, persons ages 19 years or older who have never received a dose of Tdap should receive one dose of Tdap. To ensure continued protection against tetanus and diphtheria, booster doses of either Td or Tdap should be administered every 10 years throughout life.

A tetanus toxoid–containing vaccine is indicated for wound management when >5 years have passed since the last tetanus toxoid–containing vaccine dose.[54] If a tetanus toxoid–containing vaccine is indicated for persons ages 11 years or older, Tdap is preferred for persons who have not previously received Tdap or whose Tdap history is unknown. If a tetanus toxoid–containing vaccine is indicated for a pregnant female, Tdap should be used. For nonpregnant persons with documentation of previous Tdap vaccination, either Td or Tdap may be used if a tetanus toxoid–containing vaccine is indicated.[35,37,54] The pertussis booster (Tdap) may be administered regardless of the time since receipt of a

tetanus booster (Td). Two Tdap vaccine formulations (Boostrix® and Adacel®) are U.S. Food and Drug Administration (FDA) approved for use as a booster dose for children ages 10 to 18 years.[54] Recommendations for catch-up immunization of unvaccinated or undervaccinated individuals with DTaP/Tdap are available.[1,35,37] N.R. should receive the Tdap vaccination, particularly because she works in an environment with young children and she has not received a booster since her childhood DTaP series. She may be given a dose without regard to her prior tetanus booster vaccination.

Diphtheria and tetanus toxoids have been administered in combination with pertussis vaccination in the United States since the 1940s. Both diphtheria and tetanus are rare diseases in the United States as a result of universal childhood immunization. When disease does occur, it does so primarily in the elderly or those who were inadequately vaccinated.[48] For both diseases, it is the toxin-producing strains (toxigenic *Corynebacterium diphtheriae* and *Clostridium tetani*) that result in severe disease and, therefore, the vaccine antigens target the toxoids that they produce. The concentration of diphtheria toxoid in vaccine preparations for adults (designated as *d* as compared with *D* in primary vaccination) is reduced relative to those for children owing to increased reactions with repeated injections and improved response to lower antigen doses.[48] DTaP and diphtheria and tetanus toxoids (DT) are to be used for primary vaccination in children younger than age 7 years, whereas the tetanus and diphtheria toxoids (Td) are for use in children older than age 7 years and in adults. Booster doses of tetanus (Td) should be administered every 10 years.[48]

Haemophilus Influenzae b

Hib was the most common cause of bacterial meningitis and a leading cause of serious, systemic bacterial diseases in children younger than age 5 years until an effective vaccine was added to the routine immunization schedule.[55–57] The mortality rate associated with Hib meningitis was ~5%, with neurologic sequelae observed in

25% to 35% of survivors.[58,59] Epiglottitis, cellulitis, septic arthritis, osteomyelitis, pericarditis, and pneumonia also were commonly caused by *H. influenzae.* Although *H. influenzae* is associated with otitis media and respiratory tract infections, type b strains account for only 5% to 10% of these infections.[32,60]

CASE 64-7

QUESTION 1: P.M. is a 12-month-old child who has not been immunized against Hib. His parents wish to enroll him in day care and are now trying to catch him up on his immunizations.

How many doses of vaccine against Hib should he receive?

The Hib vaccine is a conjugate polysaccharide vaccine that is associated with a 95% reduction in the incidence of Hib disease in children younger than age 5 years.[60] The three currently available monovalent conjugate Hib vaccines are as follows: Hib meningococcal protein conjugate vaccine or PRP-OMP (PedvaxHIB®), Hib tetanus toxoid conjugate vaccine or PRP-T (ActHIB® and Hiberix®).[61] The immunogenicity of the conjugate vaccines are age dependent (ie, older children have an improved immune response).[60,61] The three conjugate vaccines are all approved for use in infants, the group at greatest risk for *H. influenzae* infection; however, they vary in their dosing regimens. The HbCV immunization series requires a priming series followed by a booster dose at 12 to 15 months. PRP-OMP's primary series is administered at ages 2 and 4 months in contrast to a schedule of 2, 4, and 6 months' primary series for the other vaccines.[1,35,61] Ideally, the primary series should be completed with the same HbCV; however, data support the interchangeability of the products for the priming and booster doses.[35,62] If PRP-OMP is used in a priming series with another HbCV, the number of doses necessary to complete the series for the other product should be administered.[62] Combination vaccines may also be used according to indications for each (see Table 64-2).[35,62]

The number of doses of HbCV vaccine needed in previously unimmunized older infants and children depends on their age at presentation. Children who begin HbCV at ages 7 to 11 months should receive a primary series of two doses of a vaccine containing PRP-T, or PRP-OMP followed by a booster dose at age 12 to 18 months administered at least 2 months after the previous dose.[35,62] Children ages 12 to 15 months should receive a primary series of one dose followed by a booster dose 2 months later. If a child reaches age 15 months without receiving HbCV, only one dose is necessary.[35,62] HbCV is not routinely recommended in children younger than age 5 years or in adults. Adults who have anatomic or functional asplenia or sickle cell disease, or are undergoing elective splenectomy should receive one dose of Hib vaccine if they have not previously received Hib. Adults with a hematopoietic stem cell transplant (HSCT) should receive three doses of Hib in at least 4-week intervals 6 to 12 months after transplant regardless of their Hib history. Hib is not routinely recommended for adults with HIV infection because their risk factor for Hib infection is low.

Polio

Polio, an infectious disease caused by a highly contagious enterovirus, can strike at any age, but primarily affects children younger than age 3 years (>50% of cases). The three identified serotypes of poliovirus are transmitted person to person by direct fecal–oral contact or indirect exposure to infectious saliva, feces, or contaminated water.[63,64] After household exposure, 90% of susceptible contacts become infected.[63] The poliovirus enters through the mouth and then multiplies in the throat and intestines. Once established in the intestines, the poliovirus can enter the bloodstream and invade the CNS, which may result in paralysis.[63–65]

Immunity to polio can be achieved after natural infection with poliovirus; however, infection by one serotype of the poliovirus does not protect an individual against infection from the other two serotypes.[63] Immunity can also be achieved through immunization,

and the development of effective vaccines to prevent paralytic polio was one of the major medical breakthroughs of the 20th century. Since the advent of the trivalent oral polio vaccine (OPV) and IPV, the incidence of paralytic poliomyelitis has been reduced dramatically.[65]

CASE 64-8

QUESTION 1: H.G., the mother of a 2-month-old infant, is surprised when the nurse brings in a polio vaccine injection. She remembers that she had received an oral form of the vaccine as a child.

Why is H.G.'s infant receiving a form of polio vaccine different from what she had received?

Historically, the live attenuated OPV (or Sabin vaccine) was the formulation of choice in the United States. Its advantages include low cost, ease of administration, and induction of lifelong immunity.[63] In addition, OPV provides a high level of gastrointestinal immunity, thus preventing the carrier state. The fecal shedding of the attenuated OPV virus after vaccination is also an effective way to immunize or boost the preexisting immunity in close contacts.[63],[65] Despite these benefits, OPV carries the risk of vaccine-associated paralytic polio (VAPP), especially after the first dose in immunocompromised patients such as those with B-lymphocyte disorders (eg, agammaglobulinemia, hypogammaglobulinemia).[64] In contrast to OPV, the enhanced IPV (IPOL®), which is administered IM, has not been associated with VAPP or other reactions.[64],[66] Although IPV provides systemic immunity similar to that of OPV, it induces less immunity in the gastrointestinal tract.[63],[64] The risks of VAPP from OPV, despite its high efficacy, have resulted in the recommendation of IPV as the preferred dosage form for childhood immunization.[1],[35],[65]

The ACIP and AAP guidelines recommend that all children should receive four doses of IPV at ages 2 months, 4 months, 6 to 18 months, and 4 to 6 years. The first dose of vaccine should be administered no sooner than 6 weeks of life.[66] The last dose of the

four-dose series should be administered after age 4 years and at least 6 months after the previous dose.[35],[66] Combination vaccines containing IPV are available and may be used to provide the initial four IPV doses. When Pentacel® is used, an additional IPV booster dose is recommended to ensure adequate immunity. The IPV booster dose should be administered at ages 4 to 6 years, which results in a total of five doses; this is acceptable as long as it is delivered at least 6 months after the fourth dose[65] (see Table 64-2).

CASE 64-9

QUESTION 1: L.G. is a 28-year-old graduate student who is planning extensive travel through the African continent and is concerned about polio because she had not been immunized as a child.

What would be a prudent immunization schedule for her if her trip includes travel to a polio-endemic area?

Routine poliovirus vaccination of persons older than age 18 years is not necessary in the United States because U.S. residents are at minimal risk for exposure. Vaccination, however, should be considered for adults at high risk for polio exposure (eg, travel to an area endemic for polio, close contact with children who will be receiving OPV, close contact with patients who may be excreting wild polioviruses, or work that requires handling poliovirus specimens).[65],[66] IPV is the vaccine of choice because adults have a higher incidence of VAPP from OPV than do children. Ideally, L.G. should receive two doses of IPV, administered 4 to 8 weeks apart, followed by a third dose 6 to 12 months later. If exposure is likely in <8 weeks, two doses of IPV should be administered at least 4 weeks apart.[65] If L.G.'s travel must be undertaken on short notice (<4 weeks) she should receive one dose of IPV, with receipt of the remaining doses at a later date according to schedule.[65] Even if L.G. had been immunized as a child, a single dose of IPV may be considered for booster effect.[65]

Currently, OPV is recommended only in special circumstances, such as vaccination to control outbreaks of paralytic polio,

unvaccinated infants traveling in <4 weeks to areas endemic for polio, and children of parents who reject the number of vaccine injections.[65],[66] In parents who are concerned about the number of injections, OPV may be considered for the third and fourth vaccination after receiving systemic protection with IPV for the first two doses.[65] IPV is the only poliovirus vaccine that should be used in patients with an immunodeficiency disorder, those receiving immunosuppressive chemotherapy, or those living with a person who is known or suspected to have these conditions.[65],[66]

Meningococcus

CASE 64-10

Question 1: J.C. is a 12-year-old female who presents for a checkup with her pediatrician. In discussion, it is found that her cousin attends a university where an outbreak of meningococcal disease recently occurred.

Should J.C. receive meningococcal vaccine?

After dramatic reductions of *Streptococcus pneumoniae* and Hib strains of meningitis secondary to conjugate vaccines, *Neisseria meningitidis* has become a more prominent cause of bacterial meningitis. The ACIP recommends routine vaccination of adolescents, with first dose at age 11 to 12 years and a booster at 16 years, persons ages older than 2 months at increased risk for meningococcal disease, and patients in at-risk groups to control outbreaks.[67] Patients with increased risk factors for meningococcal disease include those with persistent complement deficiencies, functional or anatomic asplenia, travel to countries where meningococcal disease is hyperendemic or endemic, or who are at risk during an outbreak. Patients ages 2 months to 55 years not previously vaccinated should receive the vaccination if they have persistent complement deficiency, complement inhibitor use, functional or anatomic asplenia, have HIV, are first-year college students in residential housing, military recruits, travel to countries

where meningococcal disease is hyperendemic or endemic, or who are at risk during an outbreak, or are microbiologists who are routinely exposed to *N. meningitides*.[67]

The available meningococcal vaccine (MCV) options include two different conjugate vaccines covering serotypes A, C, Y, and W-135 of *N. meningitides.* The two conjugate vaccines available (Menactra® and Menveo®), both MCV4 conjugate vaccines, are indicated for individuals ages 11 to 55 years.[67] The ACIP recommends administration of this vaccine to all persons at age 11 to 12 years (or at high school entry if there is no history of vaccination) and to unvaccinated college freshmen residing in dormitories. In addition, as stated earlier, the ACIP recommends a booster dose at around age 16 years and a two-dose primary vaccination for patients with reduced response to a single dose.

Meningococcal serogroup B vaccination is available as Bexsero® or Trumenba®.[67] It is indicated in children ages 10 years and older, with a preferred age of 16 to 18 years for administration. It may be administered to adolescents and young adults ages 16 to 23 not at increased risk based on shared clinical decision-making. Both vaccines are a two-dose series; however, they are not interchangeable. The same product should be used for all doses in a series. Patients older than age 10 years with anatomic or functional asplenia, persistent complement deficiency, or complement inhibitor use should receive a two-dose series of Bexsero®, or a three-dose series of Trumenba®. In 2019, the ACIP recommended that persons with certain medical conditions and microbiologists routinely exposed to *N. meningitidis* isolates receive a MenB booster dose 1 year after primary series completion, then every 2 to 3 years thereafter. During an outbreak, a single MenB booster dose was recommended if it had been ≥1 year since primary series completion. In both the adult and pediatric population, MenACWY vaccines may be administered simultaneously with MenB vaccines in a different injection site, if indicated.[35]

Adverse effects (eg, fever, headache, chills, malaise, and arthralgias) are relatively rare; however, the Centers for Disease Control and Prevention (CDC) and the FDA issued a warning

regarding the potential for increased risk of Guillain–Barré syndrome in patients receiving the Menactra® conjugate vaccine.[68] Over the course of a 16-month period beginning in June 2005, 15 cases were reported in the 11- to 19-year-old age group, and two cases in those older than age 20 years. All patients recovered. Despite this apparent small increased risk of Guillain–Barré syndrome, current recommendations remain the same, but monitoring of this development will continue. No cases of Guillain–Barré syndrome have been reported with Menveo®; however, surveillance is ongoing. At this time, J.C. should receive one of the two MCV4 vaccines and be advised to receive a booster dose at age 16.

Human Papillomavirus

CASE 64-11

Question 1: J.S. is a 12-year-old female who is healthy and not currently sexually active. Her mother and she would like background information including the role of the HPV vaccine and recommendations for use of the vaccine in J.S.

What information can you give them?

HPV commonly infects the genital tract and is primarily transmitted by sexual contact. Infection with HPV has been associated with cervical cancer as well as other anogenital cancers (vulvar and vaginal cancers in females and penile cancers in males), anogenital warts, and recurrent respiratory papillomatosis, and it is estimated to be the most common sexually transmitted infection in the United States.[69–71] HPV affects both sexes with similar infection rates, and it is usually asymptomatic, unrecognized, or subclinical.[69,72] Acute HPV infections typically resolve without clinical complications within 1 year; however, 10% to 15% of infections remain persistent and pose a risk of invasive cervical carcinoma and other anogenital carcinomas.[73] Although not all HPV infections cause cervical cancer, almost all (99%) cervical cancer in females is associated with a previous HPV infection.[70,71] The majority of disease associated with

HPV is caused by the HPV types 6, 11, 16, and 18, with HPV strains 16 and 18 accounting for 64% of invasive HPV-associated cancers and ~50% of cervical cancer precursors.[71,74,75] In contrast, HPV strains 6 and 11 account for the cause of 90% of genital warts and most cases of recurrent respiratory papillomatosis.[76,77] Infection with one strain of HPV does not prevent infection from other strains; thus, repeated infections can occur through one's lifetime, and those with prior HPV infections benefit from immunization as well.[73]

A nine-valent vaccine (Gardasil® 9) is available for the prevention of HPV infection in both males and females ages 9 to 45 years old.[78] Gardasil® is indicated for the purpose of prevention of genital warts; anal, oropharyngeal, and head and neck cancers; and other precancerous lesions.[78]

Routine vaccination with any HPV vaccine is recommended for patients at age 11 to 12 years and may begin at age 9 years.[71,79] Vaccination at this age attempts to achieve an immune response before the sexual debut and involves a two-dose series administered at intervals of 0 and 6 to 12 months for patients initiating vaccine before 15 years old.[69,71] Immunization against HPV is 90% effective in reducing persistent HPV infections and 100% effective in preventing HPV-related diseases such as genital warts or lesions.[76,77] The vaccine dosing schedule is set at two or three doses, depending on the age of initial vaccination.[71] If initial vaccination is given at age 9 to 14 years, a two-dose series at 0 and 6 to 12 months is recommended. If initial vaccination is given at 15 years or older, a three-dose series at 0, 1 to 2 months, and 6 months is recommended, with the minimum interval between doses one and two of 4 weeks, between doses two and three of 12 weeks, and doses one and three of 5 months. There is no need to restart the series if the schedule is interrupted, and the number of recommended doses is dependent on the age at patient's first dose.[71] ACIP recommends that victims of sexual abuse or assault begin vaccination at age 9, that patients with immunocompromising conditions receive the three-dose series, and that HPV vaccination should be delayed until after pregnancy.[79] For patients older than age 27 years through age 45 years who have been adequately

vaccinated, discussion of the benefit of catch-up vaccination through shared decision-making should occur.[79]

The current vaccination rates for HPV vaccination increased between 2018 and 2019, and more teens are beginning the vaccination series on time. This is likely secondary to efforts at the local, state, and federal levels and simplifying the dosing schedule.[80] The CDC recommends immunization for adolescents, regardless of current sexual activity, to decrease the lifetime risk of HPV infections and HPV-associated diseases to protect against infection when the time that an individual chooses to become sexually active comes.[77],[79] Based on the current recommendations, J.S. should receive the HPV vaccine.

Pneumococcus

CASE 64-12

QUESTION 1: M.T. is a 5-year-old male with a history of asthma. His pediatrician recommends that he receive the pneumonia vaccine.

What is the evidence behind this recommendation?

S. pneumoniae (pneumococcus) infection can cause meningitis, pneumonia, sinusitis, and otitis media, and it is a major source of illness and death among children and adults.[81–83] Infants, young children, and older patients are at highest risk for exhibiting pneumococcal infections.[81] The risk factor for disseminated pneumococcal infections is increased by underlying medical conditions (heart failure, chronic obstructive pulmonary diseases), chronic liver disease (eg, cirrhosis), functional or anatomic asplenia (eg, sickle cell disease, splenectomy), and acquired or inherited immunosuppressive conditions (eg, HIV, cancer, immunosuppressive therapy).

Several pneumococcal vaccines are available: the original polysaccharide vaccine (Pneumovax®, PPSV 23) and conjugate pneumococcal vaccines (Prevnar®, PCV 13; Vaxnuevance™, PCV

15, and Prevnar 20™, PCV 20).[81,82,84] Pneumovax® contains 23 of the most prevalent or invasive purified capsular-polysaccharide antigen types of *S. pneumoniae.* Antibody response to Pneumovax® is inconsistent in children younger than age 2 years partially because the antigens included in Pneumovax® protect against strains that typically cause adult disease, but not childhood disease. In contrast, the conjugate pneumococcal vaccines (Prevnar 13®) improve immunogenicity and efficacy in infants and toddlers.[82] The PCV 13 vaccine provides protection against the 13 pneumococcal strains that cause 90% of all pneumococcal invasive diseases in children younger than age 6 years.[85] The ACIP recommends giving the conjugate 13 vaccine (PCV 13) to all children ages 2 to 59 months and children ages 60 to 71 months with underlying medical conditions that place them at high risk for experiencing pneumococcal disease or its complications.[82] Because M.T. has already passed the recommended age for vaccination and has asthma, he should receive the PCV 13 vaccine today.

Immunocompromised patients typically have an unreliable response to vaccines, but because of the potential benefits, the pneumococcal vaccines should be administered. PCV 13 and PPSV 23 are recommended for children 6 to 18 years old with immunocompromising conditions, functional or anatomic asplenia, cerebrospinal fluid leaks, or cochlear implants.[83,86] In children, PCV 13 should be administered first, followed by PPSV 23 after 8 weeks, and a second PPSV 23 dose 5 years later.[86]

Case 64-12, Question 2: M.T.'s grandfather is 68 years old, a previous smoker, and has cardiovascular disease. Should M.T.'s grandfather receive pneumococcal vaccine?

PCV 13 vaccination in children has caused significant decline in PCV 13–type pneumococcal disease in adults.[87] In the adult population, one dose of PCV 15 or 20 is recommended to be administered to adults ages 65 years and older who have not received a PCV vaccine in the past or whose vaccination history is

unknown and in adults ages 19 to 64 years with certain underlying medical conditions or other risk factors.[84] These underlying medical conditions or risk factors include immunocompetent patients with chronic heart disease, chronic lung disease, diabetes mellitus, cerebrospinal fluid leaks, cochlear implants, alcoholism, chronic liver disease, functional or anatomic asplenia, cigarette smoking, sickle cell disease or other hemoglobinopathies, chronic renal failure, nephrotic syndrome, immunodeficiency, iatrogenic immunosuppression, generalized malignancy, HIV, Hodgkin disease, leukemia, lymphoma, multiple myeloma, and solid organ transplants.[37],[38],[84] If PCV 15 is used, a dose of PPSV 23 should be given 1 year later.[84] Adults who received PPSV 23 previously may receive a PCV vaccine 1 year after their last PPSV 23 dose.[84] If PCV 15 is used, there is no need to deliver another dose of PPSV 23.[84]

M.T.'s grandfather (a previously unvaccinated 68-year-old male) should receive one dose of PCV 15 or 20. If PCV 15 is used, it should be followed by a PPSV 23 vaccine 1 year later.

Influenza

Annual influenza vaccination is the most effective method for preventing influenza viral infections, complications, and sequelae.[88] Recommendations for influenza vaccination include anyone older than age 6 months who does not have a contraindication.[88] Routine vaccination has been supported since 2010, and clinical evidence confirms that annual influenza vaccination is a safe and effective preventative health measure with potential benefit for all ages of the population.[88] Vaccination should occur before the onset of influenza virus within the community and patients should receive their dose as soon as available, preferably by the end of October.[88]

Each year, the influenza vaccine is formulated to contain four inactivated influenza virus strains (usually, two type A and one or two type B) predicted to be in circulation within the United States during the upcoming flu season.[88] The vaccine is available in IM-administered formulations including the following: a quadrivalent

inactivated influenza vaccine (IIV) standard-dose formulation, a quadrivalent recombinant influenza vaccine (RIV4), a quadrivalent cell-culture–based inactivated vaccine (ccIIV4), a quadrivalent inactivated high-dose formulation, a quadrivalent adjuvant inactivated influenza vaccine (aIIV4), and a quadrivalent intranasal live attenuated influenza vaccine (LAIV4).[88] Each season, the composition of the vaccine is evaluated; all vaccines available in the United States are quadrivalent vaccines that contain two type A strains and two type B strains.[88]

The injectable IIV is indicated for use in children at least 6 months old to adults, including those with high-risk conditions.[88] Standard- and high-dose nonadjuvanted IIV are available.[88] The LAIV4 (intranasal) is indicated for use in healthy nonpregnant patients ages 2 to 49 years old.[88] The RIV4 and ccIIV4 are considered safe for use in patients with a history of anaphylactic egg allergy.[88] The RIV4 is indicated in patients older than 18 years, whereas the ccIIV4 is indicated in patients 2 years or older.[88]

Influenza vaccine should be administered annually for adequate protection. Children younger than 9 years old require two doses of the vaccine administered 1 month apart to achieve adequate antibody response during the first season they are vaccinated.[88] Influenza vaccine contains a small amount of egg protein, and historically it has been contraindicated in patients with a severe egg allergy.[88] Evidence indicates that even patients with severe egg allergies, including hives, or those who can eat lightly cooked eggs can safely receive the influenza vaccine in the setting of health care personnel in case anaphylactic treatment is necessary. The RIV4 and ccIIV4 are alternatives to patients with egg allergies.

One IIV4 vaccine, Afluria®, is licensed for delivery via a microinjection system into the dermis and is recommended for patients ages 18 to 64 years.[88]

CASE 64-13

Question 1: H.N. is a 72-year-old male inquiring about an influenza vaccine for older adults.

Is there a recommended vaccine for H.N.? Could he be given the LAIV instead?

Two IIV4 vaccines are indicated for patients ages 65 years and older: the high-dose IIV4 (Fluzone High-Dose®) and adjuvant IIV4 (Fluad Quadrivalent®).[88] Standard-dose inactivated quadrivalent influenza vaccines contain a total of 60 µg (15 µg of each of the four recommended strains) of influenza virus antigen per 0.5-mL dose. In contrast, Fluzone High-Dose® has four times the activity and is formulated to contain a total of 240 µg (60 µg of each strain) of influenza virus antigen in each 0.5-mL dose. The older than 65 population is targeted to receive the high-dose formulation because older patients respond with a lower antibody titer to the conventional IIV.[89],[90] Original data that supported the use of a high-dose formulation in older adults showed significantly higher antibody titers for all three influenza strains present when antibody titers were measured in patients who received a trivalent high-dose vaccine.[90–93] In a study to confirm that the high-dose influenza IIV3 improved protection against laboratory-confirmed illness, the high-dose IIV3 produced a higher antibody response and provided improved protection compared to the standard-dose IIV3.[93] The high-dose recipient rates for pneumonia, cardiorespiratory conditions, hospitalizations, nonroutine medical visits, and medication use were lower than were the standard-dose recipients, thus concluding an estimate of improved relative efficacy for the high-dose IIV3 versus the standard-dose IIV3. The safety and efficacy of the high-dose IIV4 was compared to two formulations of high-dose IIV3, with improved immunogenicity against the fourth strain of influenza as compared to the high-dose IIV3.[94] High-dose IIV4 was noninferior to high-dose IIV3 for all four strains in terms of hemagglutination inhibition geometric mean titers and seroconversion rates, but was superior at inducing higher hemagglutination inhibition geometric mean titers and seroconversion rates for both B strains when compared to high-dose IIV3.[88],[94] The safety profiles were similar in each group, with higher injection site reactions and systemic adverse reactions in the

high-dose IIV4, although categorized as mild to moderate with resolution in 3 days.[88,94]

The adjuvant IIV4 (Fluad Quadrivalent®) is also licensed for older adults ages 65 years or older.[88] The adjuvant IIV4 was compared to adjuvant IIV3, where it produced a similar immune response and was noninferior to adjuvant IIV3.[95] However, neither group met seroconversion criteria and titer thresholds for the influenza B strains.[88,95] The safety profiles were similar between the adjuvant IIV4 and adjuvant IIV3 groups, with higher injection site reactions and systemic adverse reactions in the adjuvant IIV4 group. Most of these were mild to moderate and resolved within 2 to 4 days.[88,95]

The LAIV4 (FluMist®) is available for use in healthy, nonpregnant patients ages 2 to 49 years.[96] After administration, recipients become infected with attenuated virus strains, which stimulates both local IgA and circulating IgG antibodies.[97–100] Because live attenuated influenza viral particles are present within the LAIV4, recipients may experience mild signs or symptoms related to influenza infection, such as rhinorrhea, nasal congestion, fever, or sore throat.[96] Those who should not receive or may not be able to receive the live vaccine include patients who are or have the following [88,96]:

- Severe allergy to eggs or inactive ingredients such as monosodium glutamate, gelatin, arginine, sucrose, dibasic potassium phosphate, monobasic potassium phosphate, gentamicin, or ethylenediaminetetraacetic acid
- Life-threatening reactions to previous influenza vaccinations
- Current wheezing or a history of wheezing if younger than 5 years of age
- Older than age 5 years with asthma
- Pediatric and adolescent patients currently taking aspirin therapy
- Known or suspected immunodeficiency
- History of Guillain–Barré syndrome within 6 weeks of influenza vaccine
- A history of heart, kidney, or lung disease or diabetes

- Pregnant or nursing
- Close contacts and caregivers to someone severely immuno-compromised
- Taken antiviral medications recently (oseltamivir or zanamivir within 48 hours, peramivir within 7 days, or baloxavir within 17 days)
- Cerebrospinal fluid leaks or cochlear implants
- Mild-to-moderate illness at time of vaccination
- Any underlying medical condition that predisposes to complications after influenza infection

Because of his age, H.N. should not be given the intranasal vaccine, but he could receive either the standard- or high-dose inactivated vaccine.

LIVE ATTENUATED VACCINES

Besides the live attenuated flu vaccine discussed previously, there are several other live attenuated vaccines currently available for use (see Table 64-1).

Rotavirus

Rotavirus is a major cause of gastroenteritis and subsequent dehydration in the United States. Almost all children in the United States experience rotavirus gastroenteritis within the first 5 years of their lives and up to 50% of hospitalizations secondary to gastroenteritis in children are caused by rotavirus infection.[101],[102] The AAP and the CDC currently recommend routine immunization of infants with the rotavirus vaccine.[35] There are two oral, live attenuated rotavirus vaccines currently commercially available: Rotateq® (RV5), a pentavalent vaccine, and Rotarix® (RV1), a monovalent vaccine.[103] Both vaccines are believed to be equally effective despite the lack of head-to-head comparison trials. The

RV5 vaccine is administered in a three-dose series at 2, 4, and 6 months, whereas the RV1 vaccine follows a two-dose series at 2 and 4 months.[35],[103] Initial vaccination should begin at a minimum of age 6 weeks and the maximum age at which to administer the last dose is at age 8 months.[103] It is preferred that all doses be administered with the same product; however, if a combination of RV5 and RV1 is used, a total of three doses should be administered.[103] Although immunization against rotavirus does not prevent all future episodes of rotavirus infection, it can significantly reduce the severity of infections and reduce hospitalization rates.

CASE 64-14

QUESTION 1: J.M., a 24-year-old mother, presents her 2-month-old infant to receive immunizations. She is concerned about the administration of the rotavirus vaccine because the infant's grandmother is undergoing chemotherapy for breast cancer.

Will the vaccine put her mother at risk for infection and/or cause "bowel problems" for her baby?

Because the rotavirus vaccine is a live attenuated vaccine and infants can shed the virus after administration, the immunocompromised person (the grandmother) should avoid contact with the infant's feces and adhere to good handwashing procedures, particularly during the first week after vaccine administration.[101–103] Although an immunized infant can spread the rotavirus to an immunocompromised person, the risk is believed to be small relative to the benefits and risks to the immunocompromised individual. For example, if not immunized, the infant may become infected with rotavirus and shed much higher amounts of the virus in their stool with a greater potential of spreading the illness to others. Thus, rotavirus immunization of infants under this circumstance still is strongly encouraged.[101]

The immunization of infants who themselves are immunocompromised is more controversial. Rotavirus immunization in this circumstance requires the medical practitioner to discuss risks and benefits with the infant's parents.

Despite being a live attenuated vaccine, the rotavirus vaccine may be administered at any time relative to the administration of blood products and antibody-containing products.[103] There appears to be no interference with the antibody response to the vaccine with the use of these products because much of the immune response is local within the gastrointestinal tract, which leads to protection from gastroenteritis.

Measles, Mumps, Rubella

CASE 64-15

Question 1: J.C. is a 15-month-old female who is scheduled to receive her MMR vaccination. J.C.'s mother is concerned about the risks of autism and other adverse effects from the vaccine.

How should the mother be counseled?

Measles, historically a highly contagious and common disease of childhood, often is associated with symptoms such as high fever, rash, cough, rhinitis, and conjunctivitis.

Complications, although uncommon, include pneumonia and encephalitis. Live attenuated measles virus vaccine produces a benign infection that is thought to produce lifelong immunity. Infections with measles, mumps, or rubella are uncommon in the United States secondary to a significant decrease in the incidence of measles when American children were required to receive the vaccine before entering school.[104],[105] During the 1985 to 1988 epidemic, most measles transmission occurred in areas with 95% immunization rates, indicating that some children fail to respond adequately to the initial vaccine dose.[106] In addition, up to 47% of reported cases of measles in the United States result from international importation; the remaining cases result from outbreaks in school-age children who did not receive a second dose of the vaccine.[105],[107] Unfortunately, many parents are refusing immunization

of their infants with the MMR vaccine because of unfounded media reports about the risk of autism.

The concern regarding the risk from autism after vaccination with the MMR vaccine stems from a report by Wakefield et al published in 1998. This report identified a causal relationship with the administration of the MMR vaccine and the subsequent development of autism in 12 children.[108] The results of this report became highly publicized and sparked fear in parents across the world. Further investigation revealed numerous counts of scientific misconduct for financial gains by Dr. Wakefield, which led to 10 of the 12 coinvestigators retracting their claims. The CDC has coordinated numerous investigations to uncover any relationship between the vaccine and autism, but despite years of research have been unable to find any association.

J.C.'s mother should be counseled regarding the lack of an association between autism and the MMR vaccine. If she still decides to refuse vaccination, appropriate forms for documenting such are available through the respective state's Department of Health.

The first dose of the MMR vaccine should be administered to children at age 12 to 15 months, followed by a second dose at entrance to grade school (age 4–6 years).[1,35,105] Studies indicate that infants receiving the vaccine may be at higher risk for exhibiting a febrile seizure during the 2 weeks after vaccination when peak virus replication occurs.[109] The risk appears to be higher with the combination vaccine ProQuad®. Because of this concern, the CDC recommends the preferential use of the MMR vaccine in children ages 12 to 47 months. Although studies have not shown a benefit with the use of antipyretics for preventing febrile seizures from the vaccine, it is recommended that caregivers be counseled regarding the management of fever. No increased risk of febrile seizures has been noted with the second dose of the vaccine administered at ages 4 to 6 years; thus, the use of the combination vaccine is recommended at this age to reduce the number of injections and enhance compliance.[105]

Adult vaccination with MMR vaccine is also important for protection from epidemics. Adults should receive a second dose of MMR if they were born between 1963 and 1967, previously vaccinated with killed measles vaccine, are students in postsecondary institutions, work in health care facilities, travel internationally, or were recently exposed to a measles outbreak.[105] Persons born after 1957 should receive one dose of a measles-containing vaccine.[35],[37],[105] Health care workers must show documentation of having receipt of the appropriate number of doses or laboratory evidence of immunity to comply with infection control policies.[110]

Mumps and rubella antigens are combined with measles in the MMR vaccine in the United States. Mumps illness in children rarely produces complications.[105] Meningoencephalitis generally is a benign meningitis, and postinfectious encephalitis, a serious complication, is extremely rare (1 of 6000). Deafness, commonly considered a risk of mumps, occurs rarely (1 of 15,000) and is usually unilateral. Orchitis, another complication, occurs in ~3% to 10% in postpubertal males since the postvaccine era and rarely causes sterility. The most significant consequences of rubella infection occur in pregnant patients (eg, spontaneous abortions, miscarriages, stillbirths, fetal anomalies), especially when infection occurs during the first trimester; however, the MMR vaccine is contraindicated in pregnancy.[105]

Varicella

CASE 64-16

Question 1: J.T. is a 6-year-old female who comes home from school with a note from the school nurse indicating that a child in her kindergarten class has been diagnosed with chickenpox. J.T.'s mother is quite concerned because J.T. has not been immunized with the varicella vaccine.

Will administration of the vaccine at this time protect J.T. from becoming infected?

Varivax®, a live attenuated vaccine against varicella zoster (chickenpox), is the first herpesvirus vaccine to be widely tested in healthy and high-risk children and adults.[111–113] Chickenpox is a highly contagious, mild childhood disease in healthy children, but it can be severe and even fatal, especially in the immunocompromised patient. Unusual complications (eg, severe bacterial superinfections, Reye syndrome, encephalopathies) are markedly reduced with an immunization program.[111] Before the vaccine was available, ~4 million cases of chickenpox were reported annually, with 4000 to 9000 hospitalizations and 100 deaths.[111] Historically, 55% of varicella-related deaths occurred in adults, many of whom were infected by exposure to unvaccinated preschool-aged children with typical cases of varicella.[114]

Despite high vaccine coverage rates and 85% vaccine efficacy with the previous single-dose vaccination, outbreaks of breakthrough varicella continued to occur in the United States.[111] As a result, current guidelines recommend a two-dose series for all children, adolescents, and adults without evidence of immunity.[1,35,111] The first varicella vaccine dose should be administered at ages 12 to 15 months, followed by the second dose at ages 4 to 6 years. For persons ages 7 to 12 years who have not received varicella vaccine, two doses of varicella vaccine should be administered at least 3 months apart. For persons older than age 13 years, administer two doses of varicella vaccine at least 4 weeks apart.[111]

Postexposure varicella vaccination should be considered for J.T. Chickenpox infection can be prevented or symptoms reduced if varicella vaccine is administered within 3 days of exposure and may provide some protection within 5 days.[111,113] If J.T. also needs MMR vaccination, the quadrivalent combination vaccine ProQuad® containing measles, mumps, rubella, and varicella antigens may be considered. A second dose of varicella vaccine in 3 months should be recommended to ensure long-term protection.

The most common adverse effect associated with varicella vaccine administration is rash. Transmission of the virus from the vaccine is low and caution should be used when patients exhibit a

rash postvaccination to avoid contact with immunocompromised individuals until rash resolution.[111]

Although the varicella vaccine might not entirely prevent the occurrence of chickenpox in an immunocompromised patient, it can modify the disease. In the National Institutes of Health's Collaborative Varicella Vaccine Study, a seroconversion rate of only 85% was observed after a single dose in adults, compared with 95% in healthy children and 90% in children with leukemia.[115] Varicella vaccine is generally not recommended in children who have cellular immunodeficiencies, but it can be used in those with impaired humoral immunity.[116] The vaccine should be avoided in children with symptomatic HIV, but it may be considered in asymptomatic or mildly symptomatic patients.[111]

CASE 64-16, QUESTION 2: If the varicella vaccine is now universally recommended, what is the role of the herpes zoster vaccine (HZ)?

After a primary infection with varicella, 15% to 30% of the population experiences a latent infection in the sensory nerve ganglia that reactivates, causing HZ.[111,116,117] HZ typically occurs decades after the initial varicella infection. This reactivation can result in postherpetic neuralgia or dissemination that results in skin eruptions ("shingles") and potential CNS, pulmonary, or hepatic complications.[111,116] Although some have theorized that universal varicella vaccination should eventually reduce the incidence of HZ because it prevents primary infection, others debate that the attenuated virus may have greater potential for becoming latent and reactivating.[111,116] Still others argue that with the elimination of wild-type virus in the community, the exposure of individuals with latent wild-type varicella to help boost immunity and prevent HZ is reduced. In this situation, the risk of HZ may be increased.[111,116] Routine varicella immunization began in 1995, and only long-term studies of vaccinated individuals will answer the questions about the impact of the varicella vaccination upon the incidence of HZ. However, currently, the majority of adults are not immunized against varicella

(unless required as a health care worker) and have previously acquired wild-type varicella infections. Therefore, most adults in the United States are at risk for exhibiting HZ as they age.

The zoster vaccine (Shingrix®) is a recombinant adjuvanted varicella zoster vaccine. It is approved by the FDA for all individuals older than age 50 years as a two-dose IM injection administered 2 to 6 months apart, regardless of previous HZ or history of live zoster vaccination.[35,37,116–118] Live zoster vaccine (Zostavax®) was previously marketed for patients older than age 60 years.[116,118] The recombinant adjuvanted varicella zoster vaccine (Shingrix®) is now the only zoster vaccine on the market and is recommended for patients 50 years and older, including those previously vaccinated with live zoster vaccine.[117] Shingrix® exhibits high efficacy and less waning of protection at ~4 years, even in patients older than 50 years.[117,119,120] The zoster vaccine is recommended for use in patients ages 19 and older who are (or will be) immunodeficient or immunosuppressed because of disease or therapy.[37] It has been studied in patients older than age 70 years with >90% efficacy toward HZ and 88.8% efficacy against postherpetic neuralgia.[120] It may be given to patients with a previous history of HZ, but it is not indicated to treat acute zoster, postherpetic neuralgia, or prevent further complications during an acute episode.[121] If the patient has been vaccinated with live zoster vaccine, administer Shingrix® at least 5 years afterward.[117]

COVID-19

CASE 64-17

Question 1: C.D. is a 46-year-old male inquiring about a COVID-19 vaccine for himself.

Which vaccines are recommended for C.D.?

The acute respiratory syndrome coronavirus 2 (SARS-CoV-2) emerged in late 2020 to cause a global pandemic of COVID-19 that

produces mild, moderate, or severe illness in patients of all ages with a variety of symptoms ranging from cough, fever, anosmia, ageusia, fatigue, headache, myalgias, malaise, sore throat, and diarrhea.[122–125] SARS-CoV-2 is spread by respiratory transmission of aerosols and droplets from an infected person and has an incubation period of ~4 to 5 days and symptoms within 11.5 days of infection.[124] Severe illness presents with dyspnea usually 7 days after symptom onset and can progress to acute respiratory distress syndrome, severe hypoxemia, respiratory failure, and death, most especially in older adults.[123] Because of this high morbidity and mortality and to help control the global pandemic, an accelerated development of several vaccines occurred.[15,122]

The FDA issued Emergency Use Authorization (EUA) for the first COVID-19 vaccine, the Pfizer-BioNTech COVID-19 (BNT162b2) on December 11, 2020, with full approval on August 23, 2021.[126,127] It is an mRNA vaccine that encodes the prefusion spike glycoprotein of SARS-CoV-2 into host cells to produce an immune response.[126,128] Vaccination consists of two 30-μg (0.3 mL) or 10-μg (0.2 mL) doses administered IM 3 weeks apart for patients ages 12 or older and 6 months to 11 years, respectively.[126,128] Currently, it is indicated for patients 16 and older and marketed under the brand name Comirnaty®.[128] It is also available for use under EUA for patients 6 months and older.[128–130] After two doses, 95% protection against COVID-19 after 2 months of follow-up in patients ages 16 years and older and reduced risk for severe outcomes of hospitalization and death occurred.[126,131] Immune response in patients ages 5 to 15 years was at least as high as the response observed in patients ages 16 to 25 years.[129,130,132] Local reactions including mild-to-moderate pain within 7 days of administration and redness and swelling at the injection site were more frequently reported in patients who received BNT162b2. Systemic adverse effects such as fatigue, headache, and fever were also more frequent in patients receiving the vaccine, but few had severe adverse events.[131] The BNT162b2 vaccine must be stored in an ultralow temperature freezer between −80 and −60 °C.[128] It can be stored at −25 to −15 °C

for up to 2 weeks. Refer to the product information for further storage and handling.

The FDA also issued EUA to the Moderna COVID-19 (mRNA-1273) mRNA vaccine on December 18, 2020, with full approval on January 31, 2022.[133],[134] Like the BNT162b2, the mRNA-1273 is an mRNA vaccine that encodes a spike glycoprotein to produce an immune response.[133],[135] Vaccination consists of two doses 100-µg (0.5 mL) doses administered IM 4 weeks apart.[133],[136] An extended-interval dosing series of 8 weeks between primary series doses may be optimal for some patients ages 12 years or older, especially males ages 12 to 39 years.[134] The Moderna COVID-19 mRNA vaccine is indicated for patients ages 18 years and older and marketed under the brand name Spikevax™.[136] After two doses, 94% effectiveness against COVID-19 was seen in preventing the first occurrence of symptomatic COVID-19.[135] The mRNA-1273 prevented severe illness 100%; severe illness was a secondary end point in the trial.[135] Mild-to-moderate injection site reactions after the first and second doses, most commonly an injection site reaction, occurred more frequently in patients receiving the vaccine compared to placebo.[133],[135] Local and systemic reactions, such as headache and fatigue, occurred 1 to 2 days after the vaccine dose and resolved in 2 to 3 days.[135] The incidence of severe adverse reactions was low.[135] The mRNA-1273 vaccine must be stored frozen between −50 and –15 °C.[136] It can be stored in a refrigerator between 2 and 8 °C for up to 30 days before first use, and 8 to 25°C for a total of 24 hours. Refer to the product information for further storage and handling.

In June of 2021, ACIP issued an information regarding an elevated risk factor for myocarditis among male patients ages 12 to 29 years old who received an mRNA COVID-19 vaccine.[137] ACIP reviewed the data and determined that the benefits of mRNA COVID-19 vaccines outweigh the risk of myocarditis after vaccination. However, continuing to monitor myocarditis after vaccination is necessary, and the CDC and FDA are continuing to monitor reports of myocarditis after mRNA COVID-19 vaccines.

On February 27, 2021, the FDA issued EUA to the Janssen COVID-19 (Ad26.COV2.S) adenovirus vector vaccine.[138] It is a recombinant replication-incompetent adenovirus vector vaccine that encodes a spike glycoprotein to produce an immune response.[122],[138] Vaccination is a single 0.5-mL dose administered IM and indicated for patients 18 years and older.[138] After one dose, the Ad26.COV2.S vaccine produced 66.9% effectiveness against moderate- to severe-critical COVID-19 disease.[122] Also, participants who received this vaccine and contracted moderate COVID-19 reported fewer symptoms.[122] Patients who received the vaccine did report more adverse effects compared to placebo, with the most common local reaction being an injection site reaction; the most common systemic reactions were headache, fatigue, myalgia, and nausea.[122] The incidence of severe adverse reactions was low.[122] In April of 2021, the FDA paused the use of the Ad26.COV2.S vaccine secondary to reports of thrombosis with thrombocytopenia syndrome (TTS) in patients who received this vaccine.[139] Fifteen cases of TTS were reported among 7.98 million patients who had received the Ad26.COV2.S vaccine as of April 21, 2021.[139] All patients affected were females. ACIP reviewed data and determined that the benefits of resuming the use of Ad26.COV2.S in patients 18 years or older outweighed the risks. It did add a new warning for rare clotting events among females 18 to 49 years old. In addition, cases of Guillain–Barré syndrome have also been reported after the Janssen COVID-19 vaccine.[140] Because of these events, the ACIP has made a preferential recommendation for the use of mRNA COVID-19 vaccines over the Janssen adenovirus-vectored COVID-19 vaccine.[140] The Ad26.COV2.S vaccine must be stored between 2 and 8 °C, and may be stored between 9 and 25 °C for up to 12 hours.[14] Refer to the product information for further storage and handling.

Booster doses that enhance or restore protection that has waned over time after primary vaccination are recommended for the two mRNA vaccines and the Janssen COVID-19 vaccine.[141] Conditions for a single booster of the mRNA vaccines 6 months after completion of the primary series include all adult patients ages 18 years or

older.[142] In addition, recipients 18 years or older who received the Janssen COVID-19 vaccine should receive a booster >2 months after primary vaccination. Any approved or authorized COVID-19 vaccine may be used for the booster dose. The dose and volume for the booster are the same as that for the primary vaccination for the Pfizer-BioNTech and Janssen vaccines, whereas the Moderna dose and volume of the booster is one-half of the primary series (50 μg; 0.25 mL).

The Novovax COVID-19 (NVX-CoV2373) vaccine is a recombinant nanoparticle vaccine with a Matrix-M1 adjuvant that elicits an immune response against COVID-19.[143] It is administered in two IM doses of 5 μg 3 weeks apart.[15] After two doses, 89.7% efficacy was observed against COVID-19 in preventing symptomatic mild, moderate, or severe infection.[15] The NVX-CoV2373 vaccine prevented COVID-19 hospitalization or death in the vaccine group.[15] Local injection site reactions were the most common local adverse events, and the most common systemic adverse events were headache, muscle pain, and fatigue in patients who received the vaccine.[15] It is currently not available in the United States.

Currently, C.D. would be able to receive the Pfizer-BioNTech COVID-19 (BNT162b2), the Moderna COVID-19 (mRNA-1273), or the Janssen COVID-19 (Ad26.COV2.S) vaccine.

ADMINISTRATION TECHNIQUES

Vaccines or other biologic agents are typically administered as either an IM or a subcutaneous injection.

Because appropriate administration by the correct route and technique is critical to the effectiveness of the specified vaccine, it is essential to consult the prescribing and administration information for each specific vaccination administered to a patient (see also Table 64-1). The technique of vaccine administration by either route should include sterilizing the skin surface, drawing up the vaccine from the vial into a syringe using a sterile technique, protecting the patient

and health care provider from biologic hazards, performing proper disposal of biohazardous/sharp materials (needles and blood-borne products), observing for adverse effects after administration, and reassuring the patient post the vaccine administration. **Table 64-3** includes general guidelines for safe and effective parenteral administration.

Table 64-3
Subcutaneous and Intramuscular Vaccine Administration Techniques

Patient Age	Site	Injection Area	Typical Needle Length (inch)	Needle Gauge
Birth to 12 months	Subcutaneous	Fatty tissue over the anterolateral thigh muscle	5/8	23–25
12 months and older	Subcutaneous	Fatty tissue over anterolateral thigh or fatty tissue over triceps	5/8	23–25
Newborn (0–28 days)	Intramuscular	Anterolateral thigh muscle	5/8	22–25
Infant (1–12 months)	Intramuscular	Anterolateral thigh muscle	1	22–25
Toddler (1–3 years)	Intramuscular	Anterolateral thigh muscle or Deltoid muscle of arm if muscle mass is adequate	1–1¼ 5/8–1	22–25
Children (3–18 years)	Intramuscular	Deltoid muscle or Anterolateral thigh muscle	5/8–1 1–1¼	22–25
Adults ≥19 years	Intramuscular	Deltoid muscle or Anterolateral thigh muscle	1–1½	22–25

General recommendations on immunizations-recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep*. 2011;60:1–61; Immunization Action Coalition. How to administer intramuscular (IM) route. https://www.immunize.org/catg.d/p2020.pdf. Immunization Action Coalition. Administering vaccines: dose, route, site, and needle size. Accessed November 21, 2021. http://www.immunize.org/catg.d/p3085.pdf.

CASE 64-18

QUESTION 1: B.D., a nurse from a family medicine clinic, frantically calls you because she mistakenly administered a Pneumovax® vaccination subcutaneously.

How do you respond to B.D.'s call?

The majority of vaccines, including Pneumovax®, specify IM administration. This technique involves penetration of the

appropriate muscle at a 90-degree angle. For a graphic illustration of IM vaccine administration, see http://www.immunize.org/catg.d/p2020.pdf. Sites of IM injections include the anterolateral thigh muscle in infants and toddlers and the deltoid (upper arm) muscle in children and adults.[1,144] The typical needle used to administer an IM injection is 1 inch long and 22 to 25 gauge. A shorter needle (eg, 5/8 inch) may be used for newborns, whereas a 1- to 1/2-inch needle may be needed for adults weighing >198.42 pounds (90 kg) for females and 260.15 pounds (118 kg) for males.[144,145] Multiple IM injections given in the same extremity during the same time period should be placed at least 1 inch apart.[1] Although most vaccine products specify the route of administration, Pneumovax® may be administered either IM or into subcutaneous tissue.[146] Therefore, B.D. should be reassured that she has been administered the Pneumovax® correctly because it is acceptable to administer this vaccination by either route.

Subcutaneous vaccinations involve injection of the vaccine into fatty subcutaneous tissue between the layer of skin and the layer of muscle.[1,144] Subcutaneous vaccinations are administered with a 5/8-inch needle, 23 to 25 gauge, inserted at a 45-degree angle to the skin, while pinching up on the subcutaneous tissue to prevent injection into the muscle. For a graphic illustration of subcutaneous vaccination administration, see http://www.immunize.org/catg.d/p2020.pdf. Sites of subcutaneous injections include the fatty tissue over the anterolateral thigh muscle in newborn to 1-year-old children, and fatty tissue over the triceps in 1-year-old children to adults. Multiple subcutaneous injections given in the same extremity during the same time period should be placed at least 1 inch apart.

Other routes of administration for vaccinations include the oral, intranasal, and intradermal routes. Rotavirus and oral typhoid are the only orally administered vaccines in the United States.[1] LAIV is the only intranasal vaccine, and it is administered via a nasal sprayer with a dose divider. Intradermal influenza vaccine is the only intradermally administered vaccine, and it is administered in the area of the deltoid at a 90-degree angle into the skin.[145]

LEGAL REQUIREMENTS

CASE 64-19

QUESTION 1: C.M. wants to be able to deliver immunizations at her pharmacy. What are the requirements necessary to become a pharmacist immunizer?

How are pharmacists advocates for improving population immunization rates?

Pharmacists have varying authority to administer vaccinations within the United States based on each state's Pharmacy Practice Act. The rationale for pharmacists to deliver immunizations to the public includes pharmacist accessibility in every community and overall low vaccination rates throughout the population.[147] The Department of Health & Human Services and the CDC recognized the pharmacists' unique position to promote vaccines and also influence vaccination in diverse populations through a letter from the Assistant Surgeon General.[148] This letter also acknowledged the pharmacists' contribution to increase immunization awareness in the past, but it also requested continued assistance in this endeavor through the following:

- Increasing vaccine awareness in the adult and adolescent population
- Ensuring patients' vaccine requirements are assessed when they visit pharmacies
- Offering vaccinations to patients with certain medical conditions (high risk)
- Entering adult immunizations into vaccine registries where possible
- Partnering and collaborating with local and state health departments, immunization coalitions, medical providers, and other vaccination outreach programs

The American Pharmacists Association (APhA) has developed a national competency-based certificate training program for pharmacists, and most schools of pharmacy across the country

contain or provide an opportunity to learn immunization administration within their curriculum.[149] These programs include both didactic and hands-on training and prepare the learners to be public health educators regarding immunizations, to promote vaccinations within their community, and to administer vaccines at their practice sites. APhA also provides an immunization center with resources for the practitioner (https://www.pharmacist.com/immunization-center).

Although each state's requirements regarding necessary training, protocols, and notification systems may differ, there are some standardized requirements that a pharmacist immunizer must follow. Current cardiopulmonary resuscitation certification is a common requirement for pharmacist immunizers. Immunization administration curricula typically contain information regarding basic immunology, specifics regarding vaccine information, practice implementation, legal and regulatory issues, and administration techniques.[149],[150] Each state stipulates the statutes on patient age that may receive a pharmacist-administered vaccination; what types of vaccinations pharmacists are able to administer; and the mechanism by which pharmacists are authorized to administer vaccines by physicians, such as through a prescription, collaborative drug therapy management agreement, protocol, or standing order.[151] Some states require continuing education credit maintenance specific to immunizations or vaccinations for pharmacists who immunize; some states are very specific in their requirements, and others are more general. It is important to check with the state licensing board regarding specific statutes and regulations relating to pharmacist immunization practices. In addition, all states and territories have adopted legislation allowing pharmacy interns to administer vaccines, given the student has completed an immunization certificate program and operates only under supervision of an immunizing pharmacist.[151]

Patient consent forms for immunization and vaccine information sheets are important aspects for patient safety that pharmacists are required to use as part of an approved immunization program. Consent forms should include screening questionnaires specific for

each vaccine, should be signed before vaccine administration, and should be reviewed by the pharmacist with the patient present. Vaccine information sheets have patient information developed by the CDC providing specific individual vaccine information benefits and risks, and they are required to be distributed to the patient with each vaccine by the National Childhood Vaccine Injury Act of 1986. Resources for pharmacists are available through the CDC, Immunization Action Coalition, and APhA.[150],[152],[153]

More recently, under the Public Readiness and Emergency Preparedness Act (PREP Act), the Department of Health & Human Services authorized the state-licensed pharmacists (and pharmacy interns working under a pharmacist supervisor as long as the intern is licensed and/or registered by their state board of pharmacy) to order and administer vaccines to patients ages 3 to 18 years old as long as[154]:

- The vaccine is approved by the FDA.
- The vaccine is administered according to the CDC's ACIP immunization schedules.
- The licensed pharmacist has completed the required training by the American Council for Pharmacy Education (ACPE) to administer vaccines. The training must contain at least 20 hours of ACPE training that includes hands-on injection technique, clinical evaluation of vaccine indications and contraindications, and recognition and treatment of vaccine emergency reactions.
- The licensed or registered pharmacy intern has completed the practical training by ACPE to administer vaccines. The training must include hands-on injection technique, clinical evaluation of vaccine indications and contraindications, and recognition and treatment of vaccine emergency reactions.
- The licensed pharmacist and licensed or registered pharmacy intern must have a current certificate in basic cardiopulmonary resuscitation.
- The licensed pharmacist must complete at least 2 hours of ACPE-approved immunization-related continuing education during each

state licensure period.

- The licensed pharmacist must comply with record keeping and reporting requirements of the jurisdiction of which they administer vaccines, including the patient's primary care provider when available, submitting the required immunization information to the state or local immunization information system (vaccine registry), complying with the requirement regarding reporting adverse events, and complying with requirements that the person administering a vaccine must review the vaccine registry or other vaccine records before administering the vaccine.
- The licensed pharmacist must inform their childhood vaccine patients and adult caregivers accompanying the child of the importance of well-child visits with a pediatrician or other licensed primary care provider and refer patients as appropriate.

Central Nervous System Infections

Deanna J. Buehrle and Gregory A. Eschenauer

CORE PRINCIPLES		CHAPTER CASES
1	The most common symptoms of meningitis include the triad of fever, stiff neck, and altered mental status. In neonates and infants, irritability and poor feeding may be reported along with fever. In the elderly, signs may be absent or more subtle.	**Case 65-1 (Question 1)**
2	Cerebrospinal fluid (CSF) is essential in confirming the diagnosis of meningitis. The CSF typically contains many white blood cells (WBCs) with a predominance of neutrophils. In addition, CSF protein is typically elevated to >100 mg/dL with a low CSF glucose concentration (either <50 mg/dL	**Case 65-1 (Question 2)**

	or <50%–60% of a simultaneously obtained serum glucose value).	
3	Adjunctive dexamethasone should be initiated in all patients with suspected bacterial meningitis either before or concomitant with the first dose of antibiotic.	**Case 65-1 (Question 4)**
4	The choice of empiric therapy in patients with meningitis is primarily driven by age and the presence of predisposing conditions (postneurosurgical, head trauma, immunocompromised).	**Case 65-1 (Question 3)**
5	Intraventricular antibiotics should be considered for patients with meningitis who have an external drainage device in place. Such therapy should be used in combination with systemically administered therapy.	**Case 65-4 (Question 4)**
6	Brain abscess is associated with a different spectrum of pathogens, including oral anaerobes, staphylococci, and aerobic gram-negative bacilli, depending on the patient. The barrier from the blood to brain parenchyma differs from that between blood and CSF. Consequently, the choice of antimicrobial for brain abscess may differ from that associated with meningitis.	**Case 65-5 (Questions 1–3)**
7	Response to therapy should be monitored by resolution of fever, altered	**Case 65-1 (Question 6)**

mental status, and stiff neck. A baseline level of mental status should be evaluated for this reason. Delays in response to therapy may require a repeat lumbar puncture to reexamine CSF cultures, which are usually sterile after 18 to 24 hours of therapy. Clinical response should be seen between 24 and 48 hours of initiation of therapy.

INTRODUCTION

The pharmacotherapy of central nervous system (CNS) infections presents numerous challenges. Antibiotic penetration often is limited, and host defenses are absent or inadequate. Thus, morbidity and mortality from infections of the CNS remain high despite the availability of highly potent, bactericidal antibiotics. In a review of 3155 episodes of bacterial meningitis between 1998 and 2007, the mortality rate was 15%.[1] Although eradication of bacteria is essential, it is only one of the variables that affects mortality from CNS infections. In an attempt to decrease morbidity and mortality, the pathophysiologic mechanisms of CNS infections continue to be studied.[2]

A number of infectious processes can occur within the CNS (eg, meningitis, encephalitis, meningoencephalitis, brain abscess, subdural empyema, and epidural abscess). In addition, prosthetic devices placed into the CNS (eg, cerebrospinal fluid [CSF] shunts for management of hydrocephalus) often are complicated by infection. Many etiologic agents are capable of inducing CNS infections, including bacteria, viruses, fungi, and certain parasites. This chapter focuses primarily on bacterial infections of the CNS, with an emphasis on the pharmacotherapy of bacterial meningitis and brain abscess. (Also see Chapter 76, Pharmacotherapy of Human

Immunodeficiency Virus Infection, and Chapter 77, Opportunistic Infection in Patients Living With HIV, for presentations pertaining to CNS infections in these populations.)

REVIEW OF CENTRAL NERVOUS SYSTEM

Anatomy and Physiology

MENINGES

Proper therapy for CNS infections requires an understanding of anatomic and physiologic characteristics. The brain and spinal cord are ensheathed by a protective covering known as the *meninges* and suspended in CSF, which acts as a shock absorber to outside trauma. The meninges consist of three layers of fibrous tissue: the *pia mater*, *arachnoid*, and *dura mater*. The pia mater, the innermost layer of the meninges, is a thin, delicate membrane that closely adheres to the contours of the brain. Separating the pia mater from the more loosely enclosed arachnoid membrane is the subarachnoid space, in which the CSF resides. The pia mater and arachnoid, known collectively as the *leptomeninges,* lie interior to the dura mater, a tough outer membrane that adheres to the periosteum and vertebral column. *Meningitis* is a term describing inflammation (often the result of infection) of the subarachnoid space. Abscesses also can form outside the dural space (epidural abscess), often with devastating consequences.[3]

CEREBROSPINAL FLUID

CSF is produced and secreted by the choroid plexus in the lateral ventricles and, to a lesser extent, by the choroid plexuses within the third and fourth ventricles. CSF flows unidirectionally from the lateral ventricles through the foramina of the third and fourth ventricles into the subarachnoid space, then over the cerebral hemispheres, and downward into the spinal canal. CSF is absorbed through villous

projections (arachnoid villi) into veins, primarily the cerebral venous sinuses. About 0.35 to 0.4 mL of CSF is secreted per minute, with 50% of the total volume of CSF being replaced every 5 to 6 hours.[4] The flow of CSF is unidirectional from the ventricles to the intralumbar space. Therefore, intralumbar injection of antibiotics results in little, if any, antibiotic reaching the cerebral ventricles.[3,5] This unidirectional flow of CSF presents a problem because ventriculitis commonly occurs in conjunction with bacterial meningitis. Direct intraventricular instillation of antibiotics, usually by means of a reservoir, is preferable in the setting of ventriculitis (see Case 65-4, Question 4).[6]

In adults, children, and infants, the volume of CSF is ~150 mL, 60 to 100 mL, and 40 to 60 mL, respectively.[4,7] Knowledge of approximate CSF volume facilitates estimation of the CSF concentration of a drug subsequent to intrathecal administration. For example, administration of gentamicin 5 mg (5000 µg) intrathecally should result in a CSF concentration of ~33 µg/mL in an adult shortly after administration.

The composition of CSF differs from other physiologic fluids. The pH of CSF is slightly acidic (normal pH, 7.3), and with the exception of chloride ion, electrolyte concentrations are slightly less than those in serum.[6] Under normal conditions, the protein concentration in CSF is 15 to 45 mg/dL, CSF glucose values are 50 to 80 mg/dL (~60% those of plasma), and few if any WBCs are present (<5 cells/µL).[3] When the meninges become inflamed (ie, in meningitis), the composition of the CSF is altered. In particular, the protein concentration in the CSF increases, and the glucose concentration in the CSF usually declines with meningitis. Therefore, careful evaluation of CSF chemistries is useful when establishing a diagnosis of meningitis.

BLOOD–BRAIN BARRIER

The blood–brain barrier plays a crucial role in protecting the brain and maintaining homeostasis within the CNS.[3,4] Actually, two distinct barriers exist within the brain: the blood–CSF barrier and the blood–

brain barrier. The blood–CSF barrier is characterized morphologically by porous capillaries (**Fig. 65-1**). This allows proteins and other molecules (including antibiotics) to pass freely into the immediate interstitial space. Diffusion of substances into the CSF is restricted by tightly fused cells lining the ventricular side of the choroid plexus (Fig. 65-1). Cerebral capillary endothelial cells make up the blood–brain barrier, which separates blood from the interstitial fluid of the brain. Unlike capillaries in other areas of the body, the capillary endothelia of the brain are packed closely together, forming tight junctions that, in effect, produce a barrier physiologically similar to a continuous lipid bilayer. The surface area of the blood–brain barrier is >5000 times than that of the blood–CSF barrier; thus, the blood–brain barrier plays a more important role in protecting the brain and regulating its chemical composition.[8] Many antimicrobials traverse the blood–brain barrier with difficulty (see the subsequent section on Antimicrobial Penetration into the Cerebrospinal Fluid).

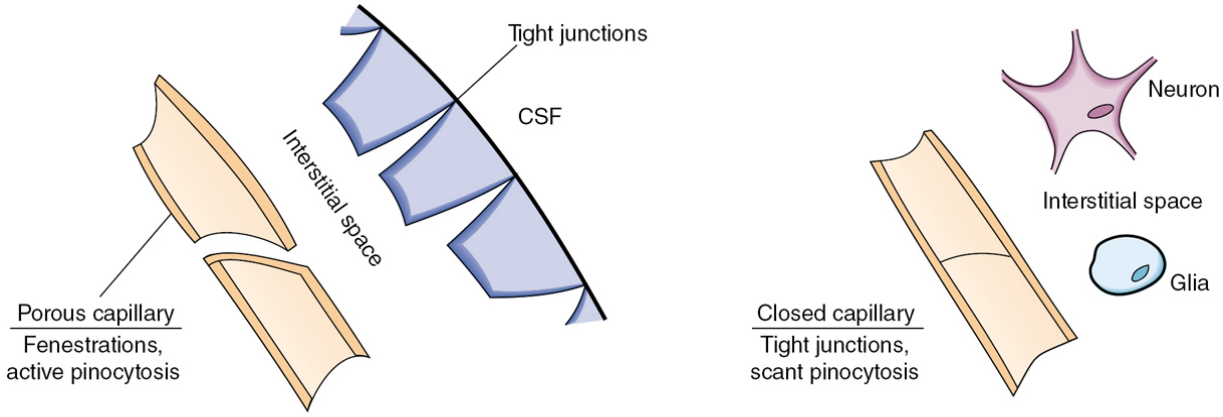

Figure 65-1 The two membrane barrier systems in the central nervous system: the blood-cerebrospinal fluid (CSF) barrier (A) and the blood-brain barrier (B). Blood-brain barrier: interface between internal medicine and the brain.

MENINGITIS

Meningitis is the most common type of CNS infection. The signs and symptoms associated with bacterial meningitis usually are acute in onset, evolving over the course of a few hours. Prompt recognition and early institution of therapy are essential to ensuring beneficial outcomes.[9] In contrast, a diverse group of infectious (eg, viruses, fungi, and mycobacteria) and noninfectious (eg, chemical irritants) agents produce a meningitic picture often of a less acute or chronic nature.[9,10] Drugs that can induce aseptic meningitis include trimethoprim–sulfamethoxazole (TMP-SMX), intravenous (IV) immunoglobulins, OKT3 antibodies, and nonsteroidal anti-inflammatory drugs such as ibuprofen, naproxen, and sulindac.[10]

Microbiology

Generally, meningitis is a disease of the very young and very old: Most cases occur in children younger than 2 years of age and in elderly adults.[1] The bacterial causes of meningitis correlate well with age and underlying conditions (**Table 65-1**).[11]

Table 65-1
Microbiology of Bacterial Meningitis

Age Group or Predisposing Condition	Most Likely Organismsa
Neonates (<1 month)	Group B streptococcus *(Streptococcus agalactiae)*, *Escherichia coli*, *Klebsiella species*, *Listeria monocytogenes*
Infants and children (1–23 months)	*S. pneumoniae, Neisseria meningitidis, S. agalactiae*, *Haemophilus influenzae*,[b] *E. coli*
Children and adults (2–50 years)	*N. meningitidis, S. pneumonia*
Adults (>50 years)	*S. pneumoniae, N. meningitidis, L. monocytogenes, E. coli*, *Klebsiella* species, and other aerobic gram-negative bacilli

Postneurosurgical	*Staphylococcus aureus*, aerobic gram-negative bacilli (eg, *E. coli, Klebsiella* species, *Pseudomonas aeruginosa*), *S. epidermidis*[c]
Closed head trauma	*S. pneumoniae*, *H. influenzae*, group A β-hemolytic streptococci
Penetrating trauma	*S. aureus, S. epidermidis*, aerobic gram-negative bacilli (eg, *E. coli, Klebsiella* species, *P. aeruginosa*)
CSF shunt	Coagulase-negative staphylococci (particularly *S. epidermidis*), *S. aureus*, aerobic gram-negative bacilli (including *P. aeruginosa*), *Propionibacterium acnes*

CSF, cerebrospinal fluid.

[a]Organisms listed in descending order of frequency.

[b]Need to consider this pathogen only in children not vaccinated with Hib.

[c]Most commonly seen in association with prosthetic devices (eg, cerebrospinal fluid shunts).

Neonates (infants younger than 1 month) are at an especially high risk for experiencing meningitis. Meningitis in preterm neonates is most often caused by *Escherichia coli*, whereas meningitis in term neonates is most often caused by group B streptococci (*Streptococcus agalactiae*). These highly virulent pathogens usually are acquired during passage through the birth canal or from the hospital environment and are associated with significant morbidity and mortality, particularly in premature infants.[1],[12] Consensus recommendations regarding intrapartum administration of penicillin to females colonized with group B streptococci have led to an 80% decrease in early-onset infection due to this pathogen.[13] *Listeria monocytogenes* is another important and often overlooked pathogen in neonates.[1] Because *L. monocytogenes* is resistant to many antimicrobial agents, including third-generation cephalosporins, selection of initial (empiric) therapy in neonates must be approached with this pathogen in mind.[11]

Infants and children 2 to 23 months old are also at a high risk for meningitis. Historically, in this age group, the disease was caused predominantly by three pathogens: *Haemophilus influenzae*, *S. pneumoniae*, and *Neisseria meningitidis*. Up to 45% of all cases of

meningitis in the United States before 1985 were caused by *Haemophilus influenzae* type b (Hib).[14] From 1991 to 1996, however, Hib invasive disease incidence in children age younger than 5 years decreased by >99%. This reduction in *H. influenzae*–induced meningitis correlates with the widespread vaccination of children against invasive *H. influenzae* disease with the Hib polysaccharide–protein conjugate vaccines.[15]

In adults and children who have received the conjugated Hib vaccine, community-acquired meningitis most often is caused by *S. pneumoniae* (the pneumococcus) and *N. meningitidis* (the meningococcus). Meningococci more commonly are implicated in individuals ages 2 to 34 years, whereas pneumococci are the predominant pathogens in adults older than age 34 years.[1] The incidence of pneumococcal meningitis has decreased by 26% from 1998 to 2006–2007 with the introduction of pneumococcal conjugate vaccines, with a decrease of 92% if only serotypes contained in the seven-valent conjugate vaccine are considered.[16] Unfortunately, use of the 13-valent conjugate vaccine has not resulted in further decreases in meningitis cases in children, with nonvaccine serotypes replacing those contained in the vaccine.[17] The incidence of meningococcal disease has decreased by 73% from 1996 to 2011. Interestingly, most of this decline in incidence occurred before the routine use of meningococcal conjugate vaccines.[18]

Patients of advanced age and those who undergo neurosurgical procedures or experience head trauma are also susceptible to meningitis. The most likely causative pathogens in these patient populations are listed in Table 65-1.

Pathogenesis and Pathophysiology

In general, meningitis can develop from *hematogenous* spread of organisms, by *contiguous* spread from a parameningeal focus (eg, sinusitis or otitis media), or by direct bacterial *inoculation*, as occurs with head trauma or neurosurgery. In contiguous spread, colonization of mucosal surfaces is a necessary first step in the

pathogenesis of meningitis. Meningeal pathogens then adhere to, and penetrate through, the epithelial surface and enter the intravascular space. Eventually, organisms that allow invasion of the blood–brain barrier multiply to sufficient numbers.[2,20,21]

Once bacteria gain entry into the CSF, host defenses are inadequate to contain the infection, and bacteria replicate rapidly. Humoral immunity (both complement and immunoglobulin) essentially is absent within the CSF. In addition, opsonic activity in CSF is negligible, and although leukocytosis ensues shortly after bacterial invasion, phagocytosis also is inefficient. Therefore, this relative immunodeficiency state necessitates the initiation of bactericidal therapy.[2,19,20]

Inflammation of the meninges is initiated by contents within the bacterial cell wall. Release of these contents (lipopolysaccharide for gram negatives and teichoic acid for gram positives) induces the production and secretion of inflammatory cytokines, which promote the adherence of leukocytes to cerebral capillary endothelial cells and facilitate the migration of leukocytes into the CSF. This results in the characteristic CSF leukocytosis as well as an eventual increase in blood–brain barrier permeability.[2,19,20]

Inflammation of the blood–brain barrier may lead to brain edema, which, combined with obstruction of CSF outflow, increases intracranial pressure and alters cerebral blood flow. Resultant hyperperfusion or hypoperfusion of the brain may ultimately result in neuronal injury, cerebral ischemia, and irreversible brain damage. The inflammatory response in meningitis also can be aggravated by some antibiotics, notably the penicillins and cephalosporins.[19] When the β-lactam antibiotics lyse bacterial cell walls, large amounts of cell wall products are liberated, and these products amplify the inflammatory response. The long-term benefits of β-lactam therapy far outweigh such detrimental effects, and the use of adjunctive corticosteroids in certain patient populations can substantially reduce inflammation and the subsequent neurologic sequelae of meningitis.[2,19,20]

In a systemic review of approximately three decades of data surrounding neurologic sequelae, the median risk of developing at

least one major or minor sequela was 19.9% (12.3%–35.3%).[21] The type and severity of neurologic complications vary with the specific infecting organism, the severity of the infection, and the susceptibility of the host. In a long-term prospective study of 185 children with acute bacterial meningitis, permanent hearing loss occurred in 6%, 10.5%, and 31% of children with meningitis caused by *H. influenzae*, *N. meningitidis*, and *S. pneumoniae*, respectively. Although seizures are fairly common on initial presentation, long-term epilepsy occurs in ~7% of patients. Other important long-term complications include spastic paraparesis, behavioral disorders, and learning deficits.[22]

Diagnosis and Clinical Features

CLINICAL AND LABORATORY FEATURES OF BACTERIAL MENINGITIS

CASE 65-1

Question 1: S.C., a 5-year-old male, is brought to the emergency department (ED) by his mother, who says her son has a temperature of 102.2 °F (39 °C), is irritable and lethargic, and has a rash. S.C. was in his usual state of good health until last night, when he awoke crying. When she went to investigate, her son began to stiffen up and rock back and forth in his bed. Because he was not arousable, S.C.'s mother rushed him to the hospital. S.C.'s medical history is noncontributory except for an allergy to amoxicillin described as a skin rash. S.C., his parents, and his 7-year-old brother recently moved to the United States. S.C.'s vaccination history currently is unknown. S.C. and his brother currently attend a community day care center.

On physical examination, S.C. was in marked distress, with a temperature of 104 °F (40 °C), blood pressure of 90/60 mm Hg, and a respiratory rate of 32 breaths/minute. His weight on admission was 44.09 pounds (20 kg). Neurologic examination showed evidence of nuchal rigidity; he was lethargic and difficult to arouse. Brudzinski and Kernig sign findings were positive. On head, eyes, ears, nose, and throat examination, S.C. demonstrated photophobia (he squinted severely when the examiner shone a light in his eyes), but no evidence was noted of papilledema. A petechial rash was visible on his extremities. The remainder of S.C.'s examination was essentially normal.

Blood drawn for laboratory tests revealed the following results:

Sodium (Na^+), 128 mEq/L

Potassium (K^+), 3.2 mEq/L
Chloride (Cl^-), 100 mEq/L
Bicarbonate (HCO_3^-), 25 mEq/L
Blood urea nitrogen (BUN), 16 mg/dL
Serum creatinine (SCr), 0.6 mg/dL
Serum glucose, 80 mg/dL

The WBC count was 18,000 cells/μL with 95% polymorphonuclear (PMN) cells; the hemoglobin (Hgb), hematocrit (Hct), and platelet counts all were within normal limits.

What clinical and laboratory features that are suggestive of meningitis does S.C. display?

The clinical features of bacterial meningitis are summarized in **Table 65-2**. The most common symptoms include the triad of fever, stiff neck (nuchal rigidity), and altered mental status. When all three of these features are present, as in S.C.'s case, meningitis should be strongly suspected. Other less common signs and symptoms include headache, photophobia (unusual intolerance to light), and focal neurologic deficits, including cranial nerve palsies.[23] A positive Brudzinski sign (reflex flexion of the hips and knees produced on flexion of the neck when lying in the recumbent position) and Kernig sign (pain on extension of the hamstrings when lying supine with the thighs perpendicular to the trunk) provide physical evidence of meningeal irritation.[24] Brudzinski and Kernig signs both were positive in S.C. Seizures occur on initial presentation in up to 60% of patients and may be focal or generalized.[23] The presence of seizures or a severely depressed mental status (ie, obtundation or coma) generally is associated with a poorer prognosis.[25] According to the most recent practice guidelines for the management of bacterial meningitis, a computed tomographic (CT) scan should be obtained before lumbar puncture in patients with specific criteria. These include immunocompromised state, history of CNS disease, new-onset seizure, papilledema, abnormal level of consciousness, and focal neurologic deficit. Although controversial, brain herniation can occur when lumbar puncture is performed in patients with elevated intracranial pressure because of the pressure changes induced within the cranial vault.[11]

Table 65-2

Signs and Symptoms of Acute Bacterial Meningitis

Fever	Anorexia
Nuchal rigidity (stiff neck)	Headache
Altered mental status	Photophobia
Seizures	Nausea and vomiting
Brudzinski sign[a]	Focal neurologic deficits
Kernig sign[a]	Septic shock
Irritability[b]	

[a]See text for description of sign.

[b]Symptoms seen in infants with meningitis.

S.C. has many of the clinical features associated with acute bacterial meningitis. Furthermore, the low blood pressure (hypotension) and increased respiratory rate are characteristic findings in severe, life-threatening types of bacterial infection (eg, septic shock, meningitis) and are likely the result of endotoxin release.

The signs and symptoms of meningitis in the very young and very old differ from those in older children and adults. In neonates, signs of meningeal irritation may be absent; fever, irritability, and poor feeding are often the only symptoms manifested.[23] Because S.C. is 5 years old, accurate assessment of his mental status is challenging. Irritability (crying), as was manifested by S.C., is an important finding that suggests an altered mental status.

In elderly patients, many of the classic signs of meningeal irritation are absent as well, and the disease presentation can be subtler.[23] Therefore, given the grave consequences of a misdiagnosis, clinicians caring for infants and elderly patients must have a particularly high index of suspicion for meningitis.

Laboratory evaluation of meningitis should include serum chemistries and a hemogram as well as a detailed examination of the CSF.[23] The peripheral WBC count often is markedly elevated in acute bacterial meningitis, usually with a left shift evident on the

differential. This finding, however, is nonspecific and occurs in many acute inflammatory and infectious diseases. S.C. has a marked leukocytosis with a predominance of PMN cells on the differential.

The abrupt onset of S.C.'s clinical symptoms is consistent with an acute bacterial process rather than a fungal or viral etiology. Given his age (5 years) and the community-acquired nature of the infection, the most likely pathogens for his meningitis are *H. influenzae*, *N. meningitidis*, and *S. pneumoniae*. The presence of maculopapular lesions argues for *N. meningitidis* as the causative pathogen because this is a common finding in cases of meningococcemia or meningococcal meningitis.[20] To make an accurate clinical and microbiologic diagnosis in S.C., it is necessary to obtain CSF for analysis. Thus, a lumbar puncture is required as soon as possible.

CEREBROSPINAL FLUID EXAMINATION

Case 65-1, Question 2: The resident physician in the ED performs a lumbar puncture, which yielded the following:

Opening pressure, 300 mm Hg (normal, <20)
CSF glucose, 20 mg/dL (normal, 50%–60% of plasma glucose)
Protein, 250 mg/dL (normal, <50 mg/dL)
WBC count, 1200 cells/μL, with 90% PMN, 4% monohistiocytes, and 6% lymphocytes

The CSF red blood cell (RBC) count was 50/μL. A STAT Gram stain of CSF revealed numerous WBCs but no organisms. CSF, blood, and urine culture results are pending. How should these CSF results be interpreted?

Careful examination of the CSF is essential to confirm the diagnosis of meningitis.[7] **Table 65-3** compares the typical findings in CSF obtained from patients with acute bacterial meningitis with those seen with fungal or viral causes.[11,26,27] In acute bacterial meningitis, the CSF is often purulent, containing numerous WBCs with a predominance of PMNs, and often is turbid. CSF protein nearly always is elevated, and the CSF glucose concentration is low.[11] In contrast, CSF obtained in viral and fungal cases of meningitis usually is clear and characterized by a much lower WBC

count with a mononuclear or lymphocyte predominance. Although the CSF protein concentration often is elevated, it may be normal. A variable effect is observed with CSF glucose.[11,26,27]

Table 65-3
Cerebrospinal Fluid Findings in Various Types of Meningitis

Microbial Etiology	WBC Count (cells/μL)	Predominant Cell Type	Protein	Glucose
Bacterial	>500	PMN	Elevated	Low
Fungal	10–500	MN	Elevated	Variable
Viral	10–200	PMN or MN	Variable	Normal

MN, mononuclear cells; PMN, polymorphonuclear neutrophils; WBC, white blood cell.

MICROBIOLOGIC EVALUATION

Microbiologic evaluation should include examination of CSF by Gram stain and culture as well as cultures obtained from other potential sites of infection (eg, blood, sputum, urine). The presence of organisms on smear is indicative of a high bacterial inoculum (ie, inoculum $>10^5$ colony-forming units/mL) and is associated with a more fulminant disease.[22] The absence of organisms on Gram stain by no means rules out infection, but does make selection of empiric therapy more difficult. Although a positive Gram stain should prompt a reevaluation of empiric therapy to ensure appropriate coverage, Gram stain results should not, by themselves, prompt a narrowing of appropriate empiric therapy.[9]

S.C. has a negative Gram stain finding, which may be the result of previous antibiotic therapy or the early detection of disease. Given the negative CSF Gram stain result, S.C. must receive antibacterial therapy sufficiently broad to cover all pathogens associated with meningitis in his age group until the results from his CSF culture are available (usually within 24–48 hours). The CSF culture nearly always is positive in purulent meningitis, although CSF cultures can

be negative in a patient who clearly has meningitis, particularly with antecedent receipt of antibiotic therapy.[7] Finally, results from cultures of other sites, such as the blood, urine, and sputum (when appropriate), can yield useful microbiologic information. In 2015, a multiplex polymerase chain reaction (PCR) panel (FilmArray® Meningitis/Encephalitis Panel, BioFire Diagnostics, LLC, Salt Lake City, Utah) was marketed, which detects 14 bacterial, viral, and yeast pathogens in about an hour from a CSF sample. Unfortunately, the test is currently limited by concerns regarding sensitivity (eg, with *S. agalactiae*) and specificity (eg, false-positive results for *S. pneumoniae*).[28] Although this panel does not replace current testing approaches, technologic innovations enabling rapid and reliable pathogen identification remain a focus of ongoing research.[29]

The CSF findings in S.C. also strongly support the diagnosis of bacterial meningitis. He has a markedly elevated opening CSF pressure, CSF leukocytosis (with a predominance of PMNs), an elevated CSF protein concentration, and a depressed CSF glucose value. A few RBCs are present in the CSF, which suggests contamination with peripheral blood caused by the traumatic nature of the lumbar puncture. Precise identification of the offending organism is not possible until CSF culture results are available.
